Detergents	13–15

antifoaming agent, detergent, etc. Although the numbers have been assigned up to 40, the usual range is between 1 and 20. Materials that are highly polar or hydrophilic are assigned higher numbers than materials that are less polar and more lipophilic. Generally, those emulsifiers with an assigned value between 3 and 6 are greatly lipophilic and produce w/o emulsions, whereas those in the range between 8 and 18 are hydrophilic and produce o/w emulsions. By using this scale, it is possible to relate various emulsifiers to suitable applications. Table 3 illustrates the relationship between HLB numbers and the type of activity expected from emulsifiers. Emulsions containing nonionic emulsifiers are prepared by dissolving or dispersing the lipophilic component in the oil phase and the hydrophilic component in the aqueous phase. The two phases are heated separately and combined. Emulsions containing nonionic emulsifiers are generally low in irritation potential, stable, and have excellent compatibility characteristics. Examples 8 and 9 illustrate the use of these emulsifiers in the formulation of creams.

The Cosmetic, Toiletry and Fragrance Association's *International Cosmetic Ingredient Dictionary* (14)

Example 8 Oil-in-water cream formulation HLB 13

Part A	
Stearic acid	10.0 (% w/w)
Mineral oil	8.0 (% w/w)
White petrolatum	6.0 (% w/w)
Sorbitan monostearate	2.0 (% w/w)
Part B	
POE ^a sorbitan monostearate	1.0 (% w/w)
Water	73.0 (% w/w)
Preservative, q.s.	

Procedure: Part A is heated at 70°C until completely melted. Part B is added at 70°C and the mixture is cooled to room temperature.

^aPolyoxyethylene.

Part A	
Mineral oil	50.0 (% w/w)
White wax	15.0 (% w/w)
Sorbitan monostearate	2.0 (% w/w)
Part B	
POE ^a sorbitan monostearate	3.0 (% w/w)
Water, q.s.	30.0 (% w/w)

Procedure: Same as in Example 8.

^aPolyoxyethylene

provides an exhaustive listing of the variety of emulsion-base components, particularly the oil phase components. Over 6000 ingredients, cross-referenced to more than 25,000 trade names and synonyms, are presented. These include emulsifiers, coemulsifiers, surfactants, and stabilizers. Another source is *The McCutcheons Detergents and Emulsifiers* (15), which also lists thousands of emulsifiers and surfactants. These lists are important sources of information and help formulators in the pharmaceutical and cosmetic industry. Commonly used oils and surfactants in formulating semisolid emulsions are shown in Tables 4 and 5.

Microemulsions

Microemulsions are fluid, transparent, thermodynamically stable oil and water systems, stabilized by a surfactant usually in conjunction with a cosurfactant that may be a short-chain alcohol, amine, or other weakly amphiphilic molecule (16, 17). An interesting characteristic of microemulsions is that the diameter of the droplets is in the range of 100–1000 Å, whereas the diameter of droplets in a kinetically stable macroemulsion is 5000 Å. The small droplet size allows the microemulsion to act as carriers for drugs that are poorly soluble in water. The suggested method of preparation of microemulsions is as follows: the surfactant, oil, and water are mixed to form a milky emulsion and titrated with a fourth component, the cosurfactant, until the mixture becomes clear (18). If more oil is added to a w/o system, the system becomes cloudy, but the addition of more cosurfactant again gives a clean transparent emulsion. As illustrated in Example 10, the formulation results in clear, transparent “ringing gels” with good stability. Microemulsions are optically clear because the diameter of the particles in the colloidal system is less than one-quarter of the wavelength of incident light. Because of this effect, the particles do not scatter light and result in a transparent system (19, 20). Microemulsions, once made, must be packaged while hot

Table 4 Oil phase emulsion components

Type	Composition	Physical state
Hydrocarbon	Mineral oils	Liquid
Hydrocarbon	Petrolatum	Semisolid
Hydrocarbon	Polyethylene polymers	Solid
Hydrocarbon	Synthetic waxes	Solid
Esters	Vegetable oils	Liquid
Ester	Lanolin	Liquid
Esters	Synthetics (e.g., butyl stearate)	Liquid or solid
Alcohols	Long chain	Liquid or solid
Fatty acids	Long chain	Liquid or solid
Ethers	Polyoxyethylene	Liquid or solid
	Polyoxypropylene	Liquid or solid
Silicones	Polymers	Liquid or solid
Natural products	Plant and animal waxes	Solid

and in the liquid form. After they are cooled, they cannot be reheated and melted because they will lose transparency because of coalescence of the oil globules to a size where they reflect light.

Water-Soluble Bases

These bases contain only water-soluble components. Water-soluble bases are also referred to as greaseless because of a lack of oleaginous materials. Incorporation of aqueous solutions is difficult because they soften greatly with the addition of water. They are better used for nonaqueous or solid substances. Polyethylene glycols (PEG) make up the majority of components of the water-soluble base. PEGs may exist as liquids or waxy solids, identified by numbers that are an approximate indication

of their molecular weight. The lowest number signifies a liquid state, which transitions to a waxy solid state as the numbers increase. For example, PEG 400 is a liquid, whereas PEG 4000 is a waxy solid. Polyethylene glycol is a polymer of ethylene oxide and water represented by the formula $\text{OHCH}_2(\text{CH}_2\text{OCH}_2)\text{CH}_2\text{OH}$. They are nonvolatile, water-soluble, or water-miscible compounds and chemically inert. PEGs of interest as vehicles include the 1500, 1600, 4000, and 6000 products, ranging from soft, waxy solids to hard waxes. PEG, particularly 1500, can be used as a vehicle by itself, but better results are often obtained using blends of high- and low-molecular-weight glycols as in polyethylene glycol ointment, NF (Example 11). PEGs also serve as excellent bases for suppository insert dosage forms. Various combinations of PEGs may be used to achieve a suppository base of desired

Table 5 Emulsifiers for semisolid emulsions

Anionic	Cationic	Nonionic
Alkyl sulfates	Quaternary ammonium compounds	Polyoxyethylene alkyl-aryl ethers
Soaps	Alkoxyalkylamines	Polyoxypropylene alkyl-aryl ethers
Dodecyl benzenesulfonates		Polyoxyethylene fatty acid esters
Lactylates		Polyoxyethylene sorbitan esters
Sulfosuccinates		Polyoxyethylene-polyoxypropylene block polymers
Monoglyceride sulfates		
Phosphate esters		Sorbitan fatty acid esters
Silicones		Glyceryl fatty acid esters
Sarcosinates		
Taurates		

Example 10 Microemulsion

Mineral oil, NF	16.0 (% w/w)
Sucrose distearate	5.0 (% w/w)
Sucrose stearate	5.0 (% w/w)
Diethylamine oleylether—10 phosphate	2.0 (% w/w)
Diethylamine oleylether—3 phosphate	5.0 (% w/w)
1,3-Ethylhexane diol	2.5 (% w/w)
Propylene glycol	5.0 (% w/w)
Water	59.5 (% w/w)

consistency and characteristics. For example, PEG 1000 blended with PEG 4000 results in a higher melting product, whereas blending with a liquid polyethylene glycol lowers the melting point. Some drugs lower the melting points of PEG and, therefore, each ingredient must be considered in selecting a base. The advantage of PEG suppositories is that they may be designed to prevent melting at body temperature but rather to dissolve slowly in the body fluids. Thus, they can be prepared at temperatures higher than that of the body. They also can be stored without the need for refrigeration and do not tend to leak from the orifice on insertion because of higher melting temperatures.

PASTES

Pastes maybe defined as ointments incorporating a high percentage of insoluble particulate solids, sometimes as much as or more than 50% (2). The use of this high amount of insoluble particulate matter renders a stiffness to the system as a result of direct interactions between the dispersed particulates and by absorption of the liquid hydrocarbons from the vehicles onto the surface of the particles. Because of the stiffness, they remain in place after application and are used effectively to absorb serous secretions. Pastes as such are not suited for application to hairy parts of the body. Examples of insoluble ingredients serving as the dispersed phase include starch, zinc oxide, and calcium carbonate. Pastes

Example 11 Polyethylene glycol ointment, NF

Polyethylene glycol 3350	40 (% w/w)
Polyethylene glycol 400	60 (% w/w)

Procedure: Heat the two ingredients in a water bath to 65°C. Allow to cool and stir until congealed.

Example 12 Zinc oxide paste, USP

Zinc oxide	25.0%
Starch	25.0%
Calamine	5.0%
White petrolatum, q.s.	100%

Procedure: Titrate the calamine with the zinc oxide and starch and incorporate uniformly in the petrolatum by levigation in a mortar or on a glass slab with a spatula. Mineral oil should not be used as a levigating agent, because it would soften the product. A portion of petrolatum can be melted and used as a levigating agent if so desired.

make good protective barriers for the following reasons. In addition to forming an unbroken film, pastes also absorb and neutralize certain harmful chemicals before they reach the skin surface. This last feature is attributed to the presence of insoluble particulate matter within the paste formulations. For example, for the treatment of diaper rash, when spread over the baby's bottom, the pastes absorb irritants formed by bacterial action on urine. Pastes also provide a protective layer over skin lesions and, when covered with suitable dressings, prevent excoriation of the patient's skin by scratching. Pastes afford emollient action as do ointments. In addition, the water-impermeable film formed on application is opaque and thus can often serve as a sunblock. Pastes are less greasy than ointments because of the absorption of the fluid hydrocarbon fraction to the insoluble particles. A clinically distinctive feature, which is generally attributed to pastes, is the ability to absorb exudates by nature of the powder or other absorptive components (21). Among the few pastes in use today is zinc oxide paste (Lassar's Plain Zinc Paste) (Example 12), which is prepared by levigating and then mixing 25% each of zinc oxide and starch with white petrolatum. The product is very firm and is better able to protect the skin and absorb secretions than is zinc oxide ointment.

GELS

Gels are defined as semisolid preparations consisting of dispersions of small or large molecules in an aqueous liquid vehicle rendered jelly-like through the addition of a gelling agent (22). Gels are an intermediate state of matter, containing both solid and liquid components. The solid component comprises a three-dimensional network of interconnected molecules or aggregates that immobilizes the liquid in the continuous phase (23). Gels may be

Example 13 Carbomer 941 gel

Carbomer 941	0.5 (% w/w)
Glycerine	10.0 (% w/w)
Triethanolamine	0.5 (% w/w)
Water	89.0 (% w/w)
Preservative q.s.	

Procedure: Water, glycerine, and preservative are mixed and the carbomer added by sprinkling on the surface while constantly mixing at high speed. Triethanolamine is added with slow agitation until a clear viscous gel forms.

classified into two primary types: hydrogels, which have an aqueous continuous phase, and organogels, which have an organic solvent as the liquid continuous medium. Gels may also be classified based on the nature of the bonds involved in the three-dimensional solid network: chemical gels form when strong covalent bonds hold the network together, and physical gels form when hydrogen bonds and electrostatic and van der Waals interactions maintain the gel network (24). Gelling agents commonly used are synthetic macromolecules (e.g., carbomer 934), cellulose derivatives (e.g., carboxymethylcellulose and hydroxypropylmethylcellulose), and natural gums (e.g., tragacanth). Carbomers in particular are high-molecular-weight water-soluble polymers of acrylic acid cross-linked with allyl ethers of sucrose and/or pentaerythritol. The NF contains monographs for six such polymers: carbomers 910, 934, 934P, 940, 941, and 1342. They are used as gelling agents at concentrations of 0.5–2.0% in water. Carbomer 940 yields the highest viscosity: between 40,000 and 60,000 CP as a 0.5% aqueous dispersion. Depending on their polymeric composition, different viscosities result. Gels may be classified as two-phase or single-phase systems. A two-phase gel system consists of floccules of small distinct particles rather than large molecules, thus called

a two-phase system often referred to as a magma. Milk of magnesia (or magnesia magma), which comprises a gelatinous precipitate of magnesium hydroxide, is an example of such a system. The gel structure in the two-phase systems is not always stable and thus may thicken on standing, forming a thixotrope, and must be shaken before use to liquefy the gel and enable pouring. Single-phase systems are gels in which the macromolecules are uniformly distributed throughout a liquid with no apparent boundaries between the dispersed macromolecules and the liquid. Examples of such gels include tragacanth and carboxymethylcellulose. A typical gel formulation may contain, apart from the gelling agent and water, a drug substance, cosolvents such as alcohol and/or propylene glycol, antimicrobial preservatives such as methylparaben and propylparaben or chlorhexidine gluconate, and stabilizers such as edetate disodium. Medicated gels may be prepared for administration by various routes including topically to the skin or eye, nasally, vaginally, and rectally. Some simple gel formulations are shown in Examples 13 and 14. Example 15 gives the formulation for a firm, rigid gel.

MANUFACTURING METHODS

Ointments

There are two primary methods of manufacturing ointment dosage forms: incorporation and fusion. Each may be used on a small scale (laboratory) or large scale (industry) for the manufacture of semisolid dosage forms.

Incorporation (laboratory scale)

On a small scale, as in a pharmacy, small quantities of ointments may be prepared using a mortar and pestle or

Example 14 Carbomer 934 alcoholic gel

Carbomer 934 resin	3.0 (% w/w)
Glycerine	10.0 (% w/w)
Ethanol	40.0 (% w/w)
2-Ethylhexylamine	2.5 (% w/w)
Water	44.5 (% w/w)

Procedure: The carbomer is dispersed in the glycerine and water, and a solution of the 2-Ethylhexylamine in ethanol is added to the water solution with mixing until a clear transparent gel is formed.

Example 15 Solubilized mineral oil gel

Polyethylene glycol 3 oleyl ether phosphate	6.8 (% w/w)
Polyethylene glycol 3 oleyl ether	4.0 (% w/w)
Polyethylene glycol 5 oleyl ether	2.7 (% w/w)
Mineral oil 220 SUS	13.6 (% w/w)
2-Ethyl-1,3-Hexanediol	13.4 (% w/w)
Propylene glycol	1.4 (% w/w)
Water	68.1 (% w/w)

Procedure: All components except water are heated to 75°C. The water is added at 75°C to the oil with mixing to form a soft gel, which on stirring and cooling sets at approximately 35°C.

an ointment slab (porcelain or glass) and spatula. The finely divided drug material is dispersed into an appropriate vehicle by mixing the components or rubbing the ingredients together to form an ointment. Sometimes, nonabsorbent parchment paper may be used to cover the working surface, which is then subsequently disposed of, thus eliminating the time to clean the ointment slabs.

When incorporating solids by the method of spatulation, the ointment base is placed on one side of the slab, and the finely divided drug powder components are placed on the other side. A small portion of the powder is mixed with a small portion of the base and worked in together to form a uniform mass. The procedure is repeated with the remaining base and powdered materials until all of the components are uniformly combined and blended. A broad blade spatula, made of metal or hard plastic, may be used for this task. Hard plastic spatulas are used when a component (e.g., phenol) of the mixture sometimes reacts with the metal.

Often it is desirable to keep the particle size of powder components in an ointment to a minimum to avoid roughness or grittiness of the preparation. Methods of particle size reduction include use of the mortar and pestle and the process of levigation. In this, the finely divided powdered material is levigated thoroughly with a small quantity of ointment base to form a concentrate. Sometimes, levigating agents such as mineral oil (for oleaginous bases) and glycerin (for aqueous bases) can also be used to form smooth dispersions. The levigating agent should be physically and chemically compatible with the drug and base. The concentrate is then diluted geometrically with the remainder of the base until a uniform mix is achieved. The process of levigation is usually carried out using a mortar and pestle to reduce particle size as well as to disperse the powdered material into the concentrate. After levigation, the dispersion may either be transferred onto an ointment slab or mixed further using the mortar and pestle with the remainder of the ointment base. If the drug substance is soluble in solvents such as alcohol or water, the powdered materials are first dissolved in the solvent of choice and then incorporated with the remainder of the base using a mortar and pestle. Spatulation is inconvenient because the water- or alcohol-dissolved components are free-flowing.

When incorporating liquids or solutions of drugs into ointment bases, care must be taken to select the appropriate ointment base with regard to its capacity to accept the volume of drug in solution. To incorporate liquids into hydrophobic bases such as oleaginous bases,

Fig. 1 Stainless steel jacketed kettle with agitator. (Courtesy of Lee Industries, Inc., Philipsburg, Pennsylvania.)

the liquid solution must first be incorporated in a minimum amount of hydrophilic base and subsequently added to the hydrophobic base. Care must be taken not to exceed the liquid-retaining capacity of the bases beyond which they become too soft or semiliquid in state.

Incorporation (industrial scale)

Mechanical mixers are used to prepare ointments in large quantities, especially in the Pharmaceutical industry. Stainless steel kettle mixers may be used to manufacture hydrocarbon and water-soluble base ointments (Fig. 1). The stainless steel kettle is jacketed for heating and cooling and is equipped with a mixing device. The kettle configuration is especially well-suited for the melting and mixing of oils and waxes and for complete bottom-emptying. Depending on the formulation to be processed, the mixer may be either a propeller or an anchor-agitator design. If the formulation is primarily liquid, a propeller

Fig. 2 Double planetary mixer showing mixing patterns at different stirring speeds. (Courtesy of Charles Ross & Son Co., Hauppauge, New York.)

mixer is more suitable. If the formulation consists of solid waxes, lanolin, petrolatum, and similar components, a kettle with a removable agitator, as shown in Fig. 1, is indicated.

Planetary mixers (Fig. 2) may also be used for large-scale preparations of the ointments. Here, the finely divided powdered materials are added slowly or sifted into the vehicle (ointment base) previously placed inside the rotating mixer. On achieving a uniform consistency, the ointment preparation may be processed through the roller mill to ensure complete dispersion and reduce the size of aggregates that may have formed during processing. The roller mills force the coarsely formed ointments through stainless steel rollers to produce ointments that are uniform in composition and smooth in texture.

Fusion Process

The process of fusion uses heat to melt all or some of the components of the ointment; the mixture is then allowed to cool with constant stirring until congealed. Additional components of the ointment preparation that were not

subject to the initial melting process are added to the congealing mixture as it is being cooled and stirred. Heat-labile substances are added to the preparation after careful observation that the temperature of the mixture is sufficiently low so as not to cause decomposition or volatilization of the components.

Substances may also be added by levigating a portion of the base with the milled drug to form a concentrate. The concentrate is then added to or dispersed in the remainder of the vehicle using a mixer such as porcelain dish or glass beaker (on a small scale) or a steam-jacketed vessel (on a large scale) and allowed to cool and congeal as noted earlier. Once congealed, the mixture is rubbed with a spatula or mortar and pestle (on a small scale) or allowed to pass through an ointment roller mill (on a large scale) to ensure a uniform and smooth texture. Some common examples of components that are subjected to the fusion process include beeswax, paraffin, stearyl alcohol, and high-molecular-weight polyethylene glycols (PEG). The order of addition of components in the process of fusion plays a role in the manufacture of ointments. In general, one way to mix all components together is to choose the component with

Fig. 3 High-turbulence mixers (turboemulsifiers) of varying capacities. (Courtesy of Charles Ross & Son Co., Hauppauge, New York.)

the highest melting point and use the minimum amount of heat to melt it. Subsequently, all the other components may be added with constant stirring and cooling of the melt until the mixture is congealed. Alternatively, the component with the lowest melting point may be added first. With increasing temperature, the remaining materials may be added to melt the entire mixture and then the process of cooling and congealing followed as before.

Emulsion Products

Emulsions are prepared by means of a two-phase heat system. In the first phase, the oil phase ingredients are combined in a jacketed tank and heated between 70 and 75°C to melt or liquefy all the ingredients to a uniform state. In a separate tank, the second phase, aqueous phase

ingredients are heated together to slightly above 75°C. The aqueous phase is then slowly added to the oil phase through constant agitation. The mixture is cooled slowly with continuing agitation as the emulsion is formed. The medicinal ingredients may be added when the emulsion is in the cooling stage. Usually, these ingredients are added as concentrated slurry that has been previously milled to a finely divided state. At times, when the aqueous phase of the emulsion system is larger, a large kettle may be required with a more complex mixer. As the oil phase is heated in a kettle, the aqueous phase is prepared in a kettle almost twice the size of the oil phase kettle. This size difference accommodates the volume of the final emulsion. Both phases may be heated between 70 and 80°C. For convenience and efficiency, the oil phase kettle should be mounted directly above the aqueous phase so as to introduce the oil phase mixture into the lower emulsifying

Fig. 4 Large-scale multiagitator mixer. (Courtesy of Charles Ross & Son Co., Hauppauge, New York.)

unit. The oil phase is introduced into the aqueous phase kettle in a relatively small stream to allow rapid dispersion and emulsification by an appropriately sized agitator. For capacities of 200 gallons or less, a single high-turbulence agitator may be used in most cases. Figure 3 shows two models of a high-turbulence emulsifier consisting of three top-entering coaxial agitators including an anchor-agitator and self-adjusting Teflon scrapers for thorough mixing of the preparation. For larger batches of up to 1000 gallons, a large-scale

multiagitator mixer may be used (as shown in Fig. 4) that involves a mixer-emulsifier (for high degree of shear), a high-speed disperser (to disperse solids into viscous liquids), and an anchor-agitator (to provide maximum movement of product under low shear conditions in the mix vessel). Another design for large batches uses a double-motion, counterrotating agitation combined with a homogenizing action that allows for versatility in mixing applications (Fig. 5). After the addition of the phases, the rate of cooling is generally slow to allow for adequate

Fig. 5 Large-scale manufacturing unit (Tri-mix Turboshear) with counter-rotating mixing bars. (Courtesy of Lee Industries, Inc., Philipsburg, Pennsylvania.)

mixing while the emulsion is still in liquid form. Cooling should be at a rate consistent with the mixing of the emulsion and scraping of the kettle walls to prevent formation of congealed masses of ointment or cream, especially when the semisolid contains a large amount of high-melting substances. If drugs are introduced during the manufacture of the product, oil-soluble drugs should be dissolved in the oil phase and water-soluble drugs in the aqueous phase. All emulsions are susceptible to bacterial contamination, thus, preservative agents should be added while the emulsion is still hot to effect complete solution. To improve the stability of the oil phase, colloid mills may be used to disperse the oil phase further once the emulsion is formed. As shown in Fig. 6, a colloid mill

can be a portable unit that can be lowered into the kettle and operated as the mixing of phases continues. It operates by a shearing action of a high-speed rotor against a stationary stator with a clearance of a few thousandths of an inch. The colloid mill may also be located outside of the kettle and the emulsion pumped through it to the filling equipment or holding tank (Fig. 7). Sometimes, a homogenizer may be used to reduce the size of the oil globules by exerting a smearing action in which the emulsion is forced through a small orifice under high pressure. It is located between the emulsifying kettle and the filling line or holding tank. The advantage of the homogenizer over the colloid mill is that it does not incorporate air into the emulsion. However, the throughput

Fig. 6 Portable batch mixer on mobile hydraulic floor stand (Courtesy of Silverson Machines, Inc., East Long Meadow, Massachusetts).

of the homogenizer is 10–100 times lower than that of the colloid mill. When the emulsion is pumped from one vessel to another, an in-line colloid mill may be installed. Instead of producing an emulsion in a kettle or other vessel, several phases may be introduced into the pipeline in their proper proportions using metering pumps and emulsified en route by the action of the in-line colloid mill (Fig. 8).

Another in-line method of emulsification is the ultrasonic process, which uses a sonolator and the

principle of the Pohlman whistle (25). This process uses a very high-intensity mixing device that mechanically generates ultrasonic acoustic energy to produce emulsions and dispersions. Liquid to be processed is pumped through a special orifice, forming a flat, high-pressure stream. This jet impinges on the edge of a flat blade enclosed in a tube, causing it to vibrate at ultrasonic frequencies. Cavitation produces violent local pressure changes that act on the liquid, causing instantaneous and intense dispersion of any immiscible liquids or insoluble particles. Water-in-oil

Fig. 7 Schematic representation of colloid mill and microphotographs showing emulsion globule size before and after milling. (Courtesy of Premier Mill Corp., Reading, Pennsylvania.)

emulsions are manufactured in the same equipment as o/w emulsions except that the phases are reversed in the equipment.

Miscellaneous Preparations

Heating, melting, and cooling in a single kettle in the same manner as with ointment preparations may be used to process the water-soluble bases composed of polyethylene glycols, ranging from liquids to waxy solids. They may be allowed to cool and solidify and to be stored until needed. Then they are remelted and packaged. Gels can be processed similarly in a single mixing kettle with slow agitation to avoid air entrapment, which may occur if mixed rapidly. This is especially important because all gels appear to be transparent or translucent, and air bubbles appear as a visible contamination.

PRESERVATIVES

Semisolid dosage forms must meet acceptable standards for microbial content, and preparations that are prone to microbial growth must contain antimicrobial preservatives. Antimicrobial preservative substances are included in ointment formulations to maintain the potency and integrity of product forms and to protect the health and safety of the consumer. The USP addresses this subject in its monograph *Microbiological Attributes of Non-Sterile Pharmaceutical Products*. An ideal preservative system should have attributes such as effectiveness at low concentrations against a host of microorganisms, solubility, nontoxicity, nonsensitizing, compatibility with other components, absence of odor, stability, and inexpensive. In addition, they must have the appropriate oil/water partition coefficient and be effective at the pH level of the products.

Several sources of contamination include water, raw materials, and poor sanitation conditions during manufacture, storage, and use. As such, preparations that contain water tend to support microbial growth to a greater extent than do preparations that are water-free. In the case of emulsion manufacture, the process of heating between 70 and 80°C usually kills most of the microorganisms. However, contamination may still occur as a result of unclean transfer lines and from improperly cleaned, sanitized, and protected filling equipment. It is not unusual to use a combination of preservatives to broaden their spectrum of activity because use of a single antimicrobial compound is generally insufficient for adequate preservation.

Fig. 8 Ultra-hygienic in-line mixer. (Courtesy of Silverson Machines, Inc., East Long Meadow, Massachusetts.)

Two categories of microorganisms are cause for concern in preservation of topical semisolid products. They are those liable to cause pathogenic symptoms and include staphylococci and hemolytic streptococci, *Pseudomonas aeruginosa* and *cepacia*, and *Escherichia coli*, and microorganisms liable to cause spoilage, which include water and airborne molds and yeasts. The following section describes the properties of some commonly used preservatives (26).

Parabens

The two most widely used agents are methylparaben and propylparaben. They are effective against molds and yeasts, but less effective against bacteria. They are more effective against Gram-positive than against Gram-negative bacteria. Parabens are most active at acidic pH levels less so in alkaline media. They are usually combined; an effective combination is 0.20% methylparaben and 0.05% propylparaben.

Dowcill 200 (Dow Chemical Co., Midland, MI) is a water-soluble, broad-spectrum antimicrobial and antifungal compound. It is not inactivated by nonionic, cationic, or anionic formulations, and it is particularly effective against *Pseudomonas*. Its activity is independent of pH; effective concentration is 0.02–0.30%.

Glydant (MDMH) (Lonza, Inc. Fairlawn, NJ): dimethylol-5,5,dimethylhydantoin is a water-soluble, highly active, broad-spectrum preservative. It functions over a wide range of temperatures and pH levels. It is noncorrosive, toxicologically acceptable, and biodegradable; effective concentration is 0.005–0.10%.

Germall 115 (Sutton Laboratories, Chatham, NJ): imidazolidinyl urea is a hygroscopic water-soluble white powder compatible with essentially all cosmetic ingredients including surfactants, proteins, and other special ingredients. Germall 115 acts synergistically with all other preservatives. It is effective against Gram-negative bacteria including *Pseudomonas*. Combined with parabens, it provides a broad spectrum of activity against yeasts and molds. It is recommended in the combination of Germall 115, 0.30%; methylparaben, 0.20%; and propylparaben, 0.01%.

Germall II (Sutton Laboratories, Chatham, NJ): diazolidinyl urea is a water-soluble, hygroscopic powder effective against Gram-positive and Gram-negative species including *Pseudomonas*. It is synergistic with other preservatives including the parabens. It is not inactivated by surfactants, proteins, or emulsifiers and is effective at all usual pH levels. It is recommended in the combination of Germall II, 0.20%; methylparaben, 0.20%; and propylparaben, 0.10%.

Germaben II-E (Sutton Laboratories, Chatham, NJ) is a clear liquid preservative system, readily soluble at a concentration of 1.0% in both w/o and o/w emulsions, but not in water alone. It has the composition of Germall II, 20%; methylparaben, 10%; propylparaben, 10%; and propylene glycol, 60%.

Suttocide A (Sutton Laboratories, Chatham, NJ) is a 50% aqueous solution of sodium hydroxymethylglycinate. It is a broad-spectrum antimicrobial preservative active against Gram-positive and Gram-negative bacteria and against yeast and mold. It remains active at alkaline pH levels.

LiquaPar Oil (Sutton Laboratories, Chatham, NJ) is a 100% clear, active, stable liquid blend of isopropyl, isobutyl, and *n*-Butyl esters of *p*-Hydroxybenzoic acid. This combination of parabens is a very effective preservative even at low concentrations against Gram-positive and Gram-negative bacteria, yeasts, and molds. The higher alkyl esters are more active and more stable and resistant to hydrolysis than are the lower alkyl esters; effective concentration is 0.1–0.4%.

Busan 1504 (CTFA) (Buckman Laboratories, Memphis, TN): dimethylhydroxy-methylpyrazole is a water-soluble, broad-spectrum bactericide and fungicide compatible with anionic, cationic, and nonionic ingredients. It is stable over a broad pH range and compatible with proteins; effective concentration is not given.

Ethylenediaminetetraacetic acid (EDTA) is a chelating agent that binds certain metals, especially iron and copper, which are essential to the nutrition of certain microorganisms. In this manner, it is a strong booster or enhancer of the activity of preservatives (27, 28) especially the parabens. Alone, it has the ability to increase the permeability of the bacterial cell wall and can kill *Pseudomonas aeruginosa* and *E. coli* by this activity; effective concentration is 0.05–0.10%.

Several factors may influence the success or failure of a preservative to protect a formulation against microbial contamination. These factors include the interaction of the preservative with surfactants, active substances, other components of the vehicle, sorption by the polymeric packaging materials, and product storage temperature. Although hundreds of chemicals can function as germicides, only a few substances have made it to the marketplace. The small list is not based as much on a compound's effectiveness as an antimicrobial agent as on the compound's safety and effectiveness in the final product.

The packaging of semisolid products, usually in jars and tubes, represents the best and worst conditions for microbial contamination. When using jars, the risk of contamination is higher every time a jar is opened or each

time fingers touch the product. For these reasons, semisolid products in jars require a highly effective, long-acting preservative system to remain active throughout the life of the product. With tubes, the risk of microbial contamination is significantly reduced because they expose only a very small area each time a cap is removed. Tubes also provide control of dose by an amount expressed with minimum exposure to the environment or human contact. Therefore, because products packaged in tubes are less likely to become contaminated, the use of preservative is also reduced. Thus, products packaged in tubes are less likely to cause skin irritation or sensitization.

PACKAGING

Topical dermatologic products are packaged in jars or tubes, whereas ophthalmic, nasal, vaginal, and rectal semisolid products are almost always packaged in tubes. Regardless of the container a semisolid product is eventually placed in, it must meet with the guidelines of the FDA (29) for drug products, as follows:

Containers, closures and other component parts of drug packages, to be suitable for their intended use, must not be reactive, additive or absorptive to the extent that the identity, strength, quality or purity of the drug will be affected. All drug product containers and closures must be approved by stability testing of the product in the final container in which it is marketed. The stability test includes testing filled containers at room temperature (e.g., 70°F) as well as under accelerated conditions (e.g., 105 and 120°F).

Because it is chemically inert, impermeable, strong, and rigid, glass has FDA clearance and is the ideal container for most drug products. With the proper closure system, it provides an excellent barrier to practically every element except light. Opaque jars are used to protect light-sensitive products and are available as porcelain white or dark green or amber in color. Commercially available empty ointment jars vary in size from 0.5 ounce to 1 pound.

Plastic containers are increasing in popularity over glass and metal (aluminum). This is because of qualities such as light weight, less breakage-prone, lower shipping costs, and the convenience of silk screen and plastic heat-transferred labeling. However, the disadvantage of plastics is the risk of permeation in two directions: from the product through the plastic from the inside out and from

the ambient environment through the plastic from the outside into the product.

Plastic containers used for emulsion systems must be thoroughly evaluated for physical and chemical changes in the emulsion as well as for physical changes in the container. Product-plastic interactions may be divided into five categories: permeation, leaching, sorption, chemical reaction, and alteration in the physical properties of the plastics or products (30, 31). For adequate protection of the product, container evaluation during the development stage of the product is imperative. The protocols and standard for tests to demonstrate resin equivalence are found in the USP/NF and include three categories of tests for chemical and spectral characteristics and moisture barrier (7). Some examples of plastics include high- or low-density polyethylene (HDPE or LDPE) or a blend of each, polypropylene (PP), polyethylene terephthalate (PET), and various plastic/foil/paper laminates, sometimes 10 layers thick (32). Each of these plastics has its own characteristics and advantages that make it conducive to packaging of semisolid products. For example, LDPE is soft and resilient and provides a good moisture barrier. HDPE provides a superior moisture barrier but is less resilient. PP has a high level of heat resistance, and PET offers transparency and a high degree of product chemical compatibility. Thus, plastics and plastic laminates are generally preferred over metal tubes for packaging of pharmaceutical and cosmetic products.

QUALITY CONTROL

The purpose of undertaking quality control measures is to ensure a quality product to the consumer. Quality control encompasses a broad range of responsibilities including component and final product testing as well as in-process testing and controls. Compliance with current Good Manufacturing Practices (cGMP) regulations, process validation, and good management of operations such as design, production, packaging, testing, and distribution are all integral parts in the total quality assurance effort. Quality control provides critical support in the testing and decision making required for process validation, and the activities and responsibilities of the quality control unit cover a broad range of testing and other activities (33). The goal of quality control is to ensure that different lots of a product are essentially the same by confirming that all lots meet specifications. The parameters used to determine the quality assurance of semisolid preparations include raw material specifications, in-process controls,

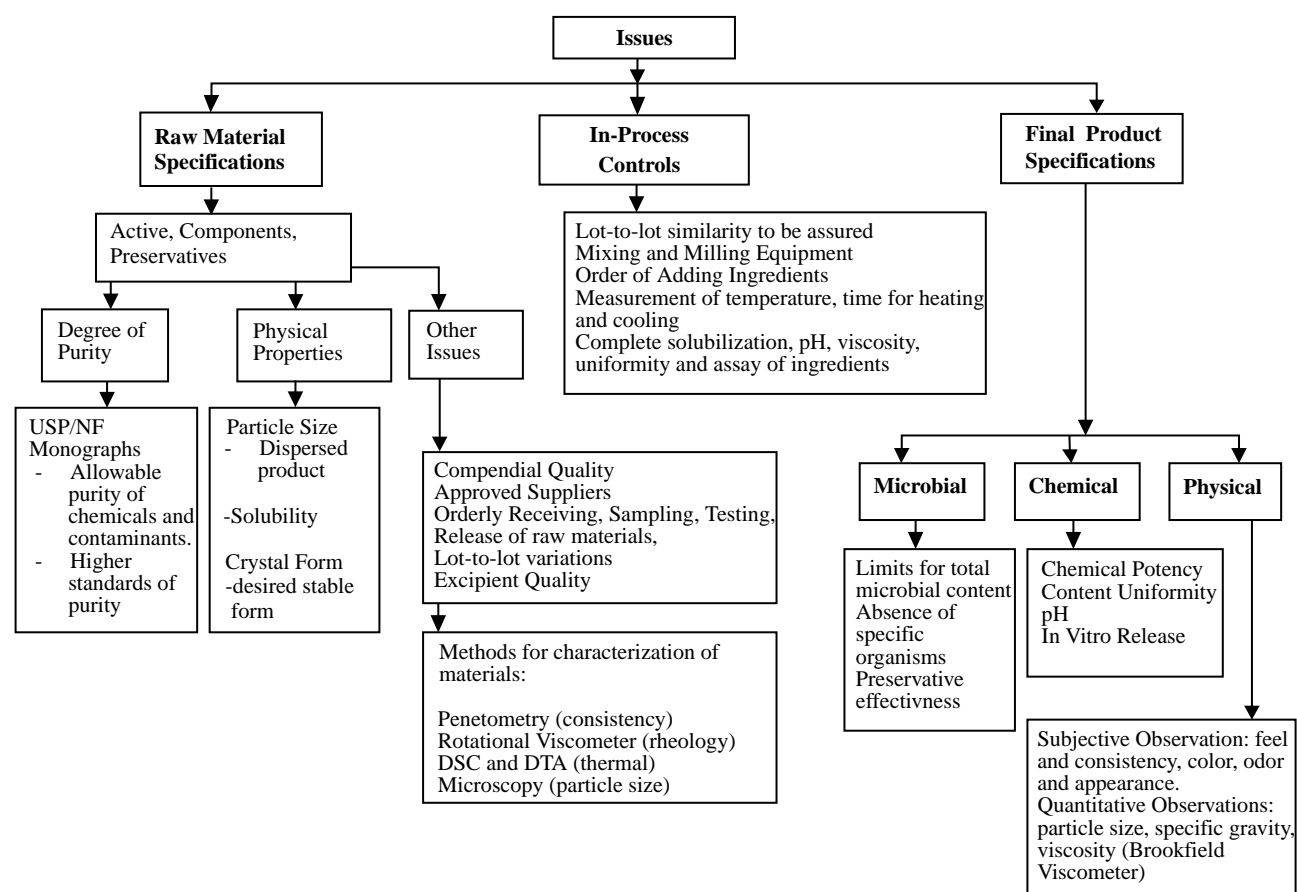

Fig. 9 Quality control of semisolid preparations.

and finished product specifications. The key parameter for any drug product is its efficacy as demonstrated in controlled clinical trials. However, the time and expense associated with such trials make them unsuitable as routine quality control methods. Therefore, *in vitro* surrogate tests are often used to ensure that product quality and performance are maintained over time and in the presence of change. As illustrated in the flow sheet (Fig. 9), a variety of physical and chemical tests commonly performed on products and their components (e.g., solubility, particle size and crystalline form of the active component, viscosity and homogeneity of the product) have historically provided reasonable evidence of consistent performance. More recently, *in vitro* release testing has shown promise as a means to comprehensively ensure consistent delivery of the active components from semisolid preparations (34). An *in vitro* release rate can reflect the combined effect of several physical and chemical parameters, including solubility and particle size of the active ingredient and rheological properties of the dosage form. In most cases, *in vitro* release rate is a useful

test to assess product sameness between prechange and postchange products. Recently, an *in vitro* test developed for a peptide containing gel formulation demonstrated that the release test can be modified to ensure product sameness after scale up and postapproval change (SUPAC) (35). However, with any test, the metrics and statistical approaches to documentation of sameness in quality attributes should be considered. Bioequivalence to previous lots may be considered as an additional parameter for some pharmaceutical products (36).

STABILITY

Stability testing is a routine procedure performed on drug substances and products. It is involved at various stages of product development. In early stages, accelerated stability testing (at relatively high temperatures and/or humidities) can be used to determine the types of degradation products that may be found after long-term

storage. Testing under more gentle conditions (those recommended for long-term shelf storage) and slightly elevated temperatures can be used to determine product shelf life and expiration dates.

According to the FDA draft guidelines to the industry (1), semisolid preparations should be evaluated for appearance, clarity, color, homogeneity, odor, pH, consistency, viscosity, particle size distribution (when feasible), assay, degradation products, preservative and antioxidant content (if present), microbial limits/sterility, and weight loss (when appropriate). Additionally, samples from production lots of approved products are retained for stability testing in case of product failure in the field. Retained samples can be tested along with returned samples to ascertain if the problem was manufacturing- or storage-related. Appropriate stability data should be provided for products supplied in closed-end tubes to support the maximum anticipated use period, during patient use, and after the seal is punctured allowing product content with the cap/cap liner. Ointments, pastes, gels, and creams in large containers including tubes should be assayed by sampling at the surface, top, middle, and bottom of the container. In addition, tubes should be sampled near the crimp.

For a product to be considered stable, it must retain the same properties and characteristics, within specific limits, that it possessed at the time of manufacture (7). A product must remain stable when it is stored for a period of time after the date of manufacture. When a product is subjected to stability testing, the objective is to determine whether the product has adequate shelf life under market and use conditions, when manufactured and packaged on a commercial scale. The FDA requires stability data on at least three lots of the same formulation and packaging—these data should appear on the product made by the commercial or any other equivalent process (in terms of critical parameters) to the proposed commercial process. To establish a stability profile, product stability storage tests must be carefully planned and initiated.

The commonly used predictive method of accelerated and stress testing depends on storage of products under conditions of rigidly controlled environment. Studies under accelerated conditions provide useful data for establishing expiration date and product stability information for future product development (e.g., preliminary assessment of proposed manufacturing changes such as change in formulation and scale up). These studies also assist in validation of analytical methods for the stability program and generate information that may help elucidate the degradation profile of the drug substance or product. Studies under stress conditions may be useful in

determining whether accidental exposures to conditions other than those proposed (e.g., during transportation) are deleterious to the product and also for evaluating which specific test parameters may be the best indicators of product stability.

A stability program typically involves aging the product under accelerated conditions of temperature, humidity, and light. Other types of accelerated or stress testing include centrifugation, shipping tests, and some form of product use test. The purpose of the product use test is primarily to evaluate preservative efficacy and ensure that the physical properties of the product remain stable under the conditions of use and are suitable for the intended application. Another useful test is to subject the product to low-intensity shaking for a period of hours or days. The key parameters of a stability program include the selection of specific accelerated storage conditions, how stability samples are stored at the test conditions (or stability stations), testing intervals, and testing the stability samples. A representative stability program may be illustrated as follows:

Samples: Each sample is one unit placed inverted in the storage chamber. An equal number of units are placed upright as control samples. The sample may also include units placed sideways. Additional samples should be placed at each stability station to make provision for samples for further investigations if this becomes necessary.

Stability Stations and Sampling Periods: Three 24-h freeze-thaw cycles are used: 1, 2, and 3 months at 50°C; 1, 3, 6, and 12 months at 40°C; and 1, 6, 12, 18, 24, and 36 months at 25°C (room temperature). At the end of each period, the sample is evaluated for chemical and physical properties as applicable (as noted earlier). The sample should also be examined to evaluate product-package compatibility. Microscopic examination of the sample can provide a very useful evaluation of changes in particle size and crystal structure. Tests for evaluating the compatibility of the product with the container include weight loss and moisture loss (if applicable). Reduction in the concentration of critical ingredients would indicate loss owing to binding with the container material or permeation through the container walls. The container should also be examined to evaluate interaction of the product with the container surface. The purpose of a stability program is to measure the changes observed in samples subjected to various stress conditions. The most difficult aspect of stability testing is to apply this information to determine the stability profile of the

product and to project an expected shelf life under market conditions. This is particularly difficult with semisolid preparations because the accelerated environmental and other stress tests used for stability testing are likely to cause substantial changes in critical properties of formulation ingredients. Higher storage temperatures can cause changes in the solubility and partitioning profile of drug and preservatives and alteration of the rheological profile of a product system. There may also be changes in the interfacial properties of ingredients that help stabilize emulsion systems. Therefore, results of stability testing can be misleading if the stress conditions used for stability evaluation do not reflect realistic product exposure conditions. It is generally recognized that application of stress testing to develop the stability profile of a product is useful. However, subjecting the product to unrealistic stress conditions is not useful for predicting shelf life under normal market and use conditions (37). Therefore, it is important to recognize the specific properties that are affected by the stress conditions of the stability test and whether the sample will return to normal after stress is removed. For this assessment, the pharmaceutical scientist must depend on the knowledge developed by appropriate studies to characterize the physical and chemical properties of the system.

SOLUBILIZATION OF DRUGS IN AQUEOUS MEDIA

Paul B. Myrdal
Samuel H. Yalkowsky

The University of Arizona, Tucson, Arizona, U.S.A.

INTRODUCTION

Therapeutic drugs are often given systemically. Once given systemically, a drug will distribute throughout the body. By distributing in the body, the drug is essentially diluted out from its original concentration in the formulation/dosage form. Hence, the formulation is really a drug concentrate. For solid dosage forms, the dose to be delivered is not normally a physical problem. However, dose can become a significant formulation challenge for parenteral preparations, due to limitations in aqueous solubility and volume. Therefore, in order to obtain a solution formulation for drugs with poor solubility, it is necessary to alter the formulation to facilitate solubilization.

The choice of solubilization method will depend upon how efficiently the drug can be solubilized, stability in the system, and upon the biocompatibility of the vehicle for a given delivery route. For solid dosage forms, it may be possible to alter the solid phase to enhance dissolution. For parenterals, the four most commonly used techniques for solubilization are: pH adjustment; cosolvent addition; micelle inclusion through surfactant addition and complexation. The following chapter is designed to summarize the theoretical as well as practical use of each of the above techniques. More extensive discussion on techniques for drug solubilization can be found in books dedicated to the subject (1, 2).

SOLUBILITY

Before attempting random laboratory experimentation, it is prudent to understand what physicochemical properties are making a given drug poorly soluble. There are two key components that govern the solubility of an organic solute in water, namely the crystal structure (melting point and enthalpy of fusion) and the molecular structure (activity coefficient). The aqueous solubility, X_w , of an organic nonelectrolyte is simply described by the addition of these two terms, i.e.,

$$\log X_w = \log X_i^c - \log \gamma^w \quad (1)$$

where X_i^c is the ideal solubility and γ^w is the activity coefficient of the compound in water.

Ideal Solubility

The ideal solubility pertains to the effect of the crystalline structure on solubility. A solute molecule must first dissociate from this crystal lattice before it can go into solution. This dissociation from the crystalline lattice is accompanied by a free energy change. The more energy it takes to free a solute molecule from its crystal (i.e., the higher the melting point), the lower the solubility.

It is possible to quantitate the molar free energy necessary to produce a hypothetical supercooled liquid at a given temperature T , through the use of an enthalpy-temperature thermodynamic cycle (3). Rigorously, it is necessary to sum the corresponding enthalpy and entropy changes that it takes to heat the crystal to the melting point, melt the crystal, then cool the liquid back to the reference temperature. For this discussion it is convenient to omit any change in enthalpy with temperature (heat capacity). This allows for the simplified mathematical expression

$$\log X_i^c = \frac{\Delta S_m(T_m - T)}{2.303RT} \quad (2)$$

where X_i^c is the ideal solubility (mole fraction), R is the universal gas constant (1.98 cal/deg mol), ΔS_m is the entropy of melting and T_m is the melting point of the compound in Kelvin.

If the entropy of melting, ΔS_m , is not known experimentally, an approximation for rigid organic molecules of 13.5 cal/degmol can be made (4). If the temperature of interest is 298 K then Eq. 2 becomes

$$\log X_i^c = -0.01(T_m - 298) \quad (3)$$

or

$$\log X_i^c = -0.01(MP - 25) \quad (4)$$

where MP is the melting point of the compound in Celsius. If the melting point is less than 25°C (i.e., liquid at room temperature) then there is no crystal limitation on solubility and Eq. 4 is equal to zero.

For those compounds that are crystalline, it is important to emphasize that the ideal solubility is strictly a function of the pure crystal, and as a result, is solvent independent. Eq. 4 also assumes that the solvent does not effect the solid phase in any way to change the free energy.

Table 1 demonstrates the effect of melting point on solubility as described by Eq. 4. It can be seen that for every 100 degree difference in melting point, there is a corresponding change in solubility of 10 times. Thus, for a hypothetical compound that melts at 325°C, the crystal structure would be responsible for approximately a 3-fold (1000 times) decrease in solubility, relative to it as a liquid at room temperature.

Activity Coefficient

The aqueous activity coefficient of a compound describes the effect of molecular structure on aqueous solubility. If a compound mixes with water and forms an ideal solution, then the activity coefficient would be taken as unity and the last term in Eq. 1 would become zero. In such a case, then the solid phase, if any, would be the sole physical property inhibiting solubility. Most drugs are relatively nonpolar and do not form ideal solutions with water. Therefore in order to understand the extent by which the inherent molecular structure is limiting solubility, it is helpful to obtain an estimate for the aqueous activity coefficient.

Numerous methods have been developed to estimate the aqueous activity coefficient (3, 5–13). A convenient method that has been successfully applied within the pharmaceutical industry utilizes the octanol/water partition coefficient. Yalkowsky and Valvani (14) have shown that the molar activity coefficient can be directly related to the octanol/water partition coefficient, $K_{o/w}$, by the following molar relationship;

$$\log \gamma^w = -\log K_{o/w} + 0.80 \quad (5)$$

Table 1 Comparison of different hypothetical melting points and the resulting effect on solubility as described by Eq. 4

Hypothetical melting point (°C)	Log X_i^c (Eq. 4)	Decrease in solubility
0	0	No effect (reference)
25	0	No effect (reference)
125	-1	10×
225	-2	100×
325	-3	1000×

There are numerous methods by which to estimate octanol/water partition coefficients. One of the most widely recognized is the group contribution method CLOGP (15).

Equation (5) enables a convenient tool for assessing the effect of structure on aqueous solubility. Table 2 demonstrates the decrease in solubility as partition coefficient increases. As $K_{o/w}$ increases by a factor of 10 ($\log K_{o/w} = 1$), the decrease in solubility is also a factor of 10. Thus, a compound with a partition coefficient of 1000 ($\log K_{o/w} = 3$) will have a solubility that is approximately 3-fold (1000 times) less than a reference compound that has a $K_{o/w}$ of 1 ($\log K_{o/w} = 0$).

Estimating Solubility

With the knowledge or estimate of the octanol/water partition coefficient and melting point, solubility can be estimated, by incorporating Eqs. 4 and 5 into Eq. 1. This gives

$$\log S_{\text{est}} = -0.01(\text{MP} - 25) - \log K_{o/w} + 0.80 \quad (6)$$

where S_{est} is the estimated molar solubility, MP is the melting point (°C) and $K_{o/w}$ is the octanol/water partition coefficient. For drugs that are liquid at room temperature, the melting point term is zero, giving simply

$$\log S_{\text{est}} = -\log K_{o/w} + 0.80 \quad (7)$$

While Eqs. 6 and 7 are simplified equations for estimating aqueous solubility, they can also be used to facilitate the understanding of why a drug is poorly soluble. The equations yield quantitative descriptions of which physicochemical properties are limiting solubility. If a compound has a low, or no melting point at room temperature, however and a high $\log K_{o/w}$, then molecular structure is limiting solubility and the aqueous media must be modified to facilitate solubilization. If the melting point is very high, and the $\log K_{o/w}$ is low, then modification of the aqueous media may not significantly increase solubility and manipulation of the solid phase may be necessary. If a compound has a high melting point and a high $\log K_{o/w}$, it can be appreciated that a formulator will have a significant challenge in drug solubilization.

Table 2 Comparison of different hypothetical $\log K_{o/w}$ s and the resulting effect on solubility as described by Eq. 5

$K_{o/w}$	$\log \gamma^w$ [Eq. 5]	Decrease in solubility
1	-0.8	Reference
10	-1.8	10×
100	-2.8	100×
1000	-3.8	1000×

SOLID PHASE

As discussed above, the solid phase for a solute molecule is a fundamental component of a compound's solubility. Consequently, understanding and characterizing the solid phase of a drug, in a given system, is of vital importance from a formulation standpoint. A comprehensive review on the theoretical and practical aspects of solid state chemistry and the significance to the pharmaceutical industry has been given by Byrn et al. (16).

It is important to always consider, that for any raw drug substance or formulation, only one solid phase is thermodynamically stable for a given set of environmental conditions. The most stable solid will have the lowest free energy and correspondingly the lowest solubility. The unknowing use of a metastable crystal can lead to formulation stability problems with respect to solubility. In light of this, it would seem as though little can be done in regards to increasing solubility through the use of crystal modification. It is clear that the most stable crystal is the most prudent choice for suspensions. The kinetics for solvent mediated transformation are generally too rapid or too uncontrollable for a stable product. However for solid dosage forms, it may be possible to utilize a less stable solid phase due to the decreased molecular mobility in the dry state. The key determinant for success will be if the metastable form has an intrinsically high energy barrier to reversion and is well defined from a kinetic standpoint. To facilitate stability, it may be necessary to add excipients or impose packaging constraints to eliminate or slow down conversion.

Apparent Solubility and Dissolution Rate

The crystal form with the higher free energy may exhibit an apparent solubility that is higher than the true equilibrium solubility for the system. An apparent solubility increase can occur anytime the starting solid material is not the most stable for the given system. However, a metastable crystal will produce only a transient increase in solubility. The most stable crystal will eventually precipitate and the apparent solubility gain will diminish until the thermodynamic equilibrium solubility is reached. The degree of supersaturation and duration will depend on the characteristics of the starting material and on the nucleation rate and growth kinetics of the stable form. Consequently, an inherent difficulty in working with metastable systems is that the kinetics of conversion often cannot be predicted or controlled.

By virtue of having a higher apparent solubility, a metastable crystal will have an increased dissolution rate

over the more stable form. The change in mass, M , as a function of time, t , for a solute is directly proportional to its apparent solubility, S_{app} , and is given by

$$dM/dt = K \times A(S_{app} - C) \quad (8)$$

where A is the solvent accessible surface area, C is the concentration of the solute in solution, and K is a constant that includes the diffusion coefficient of the solute and other hydrodynamic properties of the system (17). Hence, the larger the apparent solubility of a metastable form, the greater the dissolution rate that it leads to. Hamlin et al. (18) have illustrated the dependency of dissolution rate upon solubility for a large number of pharmaceutical compounds. Yoshihashi et al. (19) have correlated initial dissolution rates for terfenadine based on heats of fusion of the starting material. In addition, since the crystal contribution to solubility is independent of the solvent, this general relationship is applicable to virtually any solvent system. Nicklasson and Brodin (20) have successfully correlated dissolution rate with solubility for ethanol cosolvent systems.

Surface area is also directly proportional to the dissolution rate of a solute. Particle size reduction is another common and often efficient means by which to achieve higher levels of drug in solution at earlier time points (21–28). As particle size decreases, the surface area per unit volume of solute increases and consequently more drug is exposed to the solvent. Also, as particle size decreases the surface molecules are of higher free energy which increases dissolution. And finally, the processing of solid material can often lead to crystal defects within a particle or surface area where crystallinity is lost (amorphous), both of which can increase the apparent solubility. Mosharraf et al. have demonstrated the effect of crystal structure disorder on solubility and dissolution rate (29).

The significance of solubility and dissolution is one to be highlighted. Insufficient oral bioavailability can be the result of a compound's low intestinal solubility and/or a slow dissolution rate. It may be practical at times to use a solid material that gives a higher apparent solubility and/or an increase in dissolution rate in order to enhance bioavailability. Aguiar et al. (30, 31) were able to show that polymorph B of chloramphenicol palmitate, which can produce solubility that is roughly two times that of polymorph A, gives greater blood levels in vivo. They were able to show that as the percentage of polymorph B increases in the dosage form, there is a linear increase in blood concentration of chloramphenicol palmitate. Several other investigators (32–34) have also found that with the proper choice of the solid-state form,

biological activity can be enhanced due to increased solubility or dissolution rate.

Apparent Solubility Enhancement from Different Solid Phases

In order to assess the relative increase in solubility of a metastable solid phase with respect to another, a simple solubility ratio can be defined. Here the solubility ratio is

defined as the value for the higher solubility phase divided by the lower. Table 3 contains a selected list of solubility ratios for different solid phases of a selected list of example drugs.

From Table 3, it can be seen that a solubility ratio greater than one can be obtained, however there are cases in which there is no apparent increase in solubility between phases. For the data given, the transient solubility increase for solvates is similar to that of polymorphs, having solubility ratios that often range between 1 and 3.

Table 3 Examples of different drugs and their observed solubility ratios for different solid phases^a

Drug (temp. in °C)	More soluble phase/less soluble phase	Solubility ratio	Reference
Acetohexamide (37)	II/I	1.2	35
Benzoxoprofen (25)	I/II	1.5	36
Glibenclamide (37)	II/I	1.6	37
Mebendazole	C/A	3.6	38
Mebendazole	B/A	7.4	38
Meprobamate (25)	II/I	1.9	39
Oxyclozamide (25)	II/I	2.6	40
Oxyclozamide (25)	III/I	3.9	40
Ampicillin (not cited)	Anhydrate/trihydrate	1.3	41
Ampicillin (20)	Anhydrate/hydrate	2.2	42
Ampicillin (30)	Anhydrate/hydrate	1.5	42
Calcium gluceptate (37)	Anhydrate/3.5 hydrate	18.6	43
Erythromycin (30)	Anhydrate/dihydrate	2.2	44
Lamivudine (25)	Anhydrate/0.2 hydrate	1.2	45
Paroxetine HCl (20)	Anhydrate/hemihydrate	1.7	46
Phenobarbital (20)	Anhydrate/hydrate	1.1	47
Phenobarbital (25)	Anhydrate/hydrate	1.4	47
Phenobarbital (35)	Anhydrate/hydrate	1.0	47
Piroxicam (25)	Anhydrate/monohydrate	1.0	48
Sulfamethoxazole (25)	Anhydrate/monohydrate	1.2	49
Theophylline (25)	Anhydrate/monohydrate	2.0	50
Uric acid (25)	Hydrate/anhydrate	1.6	51
Uric acid (37)	Hydrate/anhydrate	1.9	51
DMHP (25)	Formate solvate/anhydrate	8.2	52
Furosemide (37)	Dioxane solvate/anhydrate	1.3	53
Furosemide (37)	DMF solvate/anhydrate	1.2	53
Glibenclamide (37)	Pentanol solvate/anhydrate	31.8	37
Glibenclamide (37)	Toluene solvate/anhydrate	2.4	37
Caffeine (25)	Amorphous/crystalline	6.5	54
Diacetylmorphine (25)	Amorphous/crystalline	16	54
Theophylline (17)	Amorphous/crystalline	58	54
Theobromine (16)	Amorphous/crystalline	50	54
Morphine (20)	Amorphous/crystalline	268	54
Hydrochlorothiazide (37)	Amorphous/crystalline	1.1	55
Bendrofluazide (37)	Amorphous/crystalline	2.8	55
Cyclothiazide (37)	Amorphous/crystalline	6.2	55
Cyclopenthiazide (37)	Amorphous/crystalline	8.3	55
Polythiazide (37)	Amorphous/crystalline	9.8	55

^aThe different solid phases used as well as the temperature of the experiment study are also given.

While most compounds produce increases that are less than a factor of ten, calcium gluceptate and glibenclamide exhibited significant increases of nearly 20 and 30, respectively (37, 43).

Consideration of Eq. 4, would suggest that the largest gain in solubility should be realized for those solid fractions that are actually not crystalline, i.e., amorphous. For a purely amorphous material, there would be no crystal contribution to the solubility and the compound could be treated as a liquid. Since it is difficult to produce a purely amorphous material, there is often some degree of crystallinity to a "amorphous" material. Nonetheless, amorphous materials clearly have the highest free energy, relative to any crystalline solid fraction. As a result, amorphous materials can potentially give some of the largest solubility ratios. Toffoli et al. (54) and Corrigan et al. (55) have investigated the use of amorphous materials and have found a wide range of apparent solubility ratios. Some of their data is listed in Table 2, and clearly shows that the use of an amorphous material has the greatest potential for solubility enhancement. Other investigators have also observed significant solubility differences with amorphous compounds (56–58). Some investigators have seen practical in vivo benefits by using amorphous materials (59, 60). However, due to the high free energy of these systems their use is often not practical. Giron (61) has noted a few compounds that have relatively stable amorphous forms.

Through alteration of the solid-state form it is possible to increase the dissolution rate, or apparent solubility of a drug. These increases can potentially increase the bioavailability of a poorly water soluble drug. However, the practical use of a higher energy solid form is limited due to physical and chemical stability issues. Significant investigation must be made in order to assure that a dosage form using a metastable crystal will maintain integrity throughout the product life.

pH CONTROL

Solid-state manipulation is often not advantageous or practical, as a result, it is then necessary to alter the solvent. For organic solutes that are ionizable, changing the pH of the system may be the simplest and most effective means of increasing aqueous solubility.

For a weak monoprotic acidic drug, $HA_{(solid/liquid)}$, in water:

where $HA_{(solution)}$ represents the free acid (unionized form) in solution and A^- is the ionized acid in solution. The total concentration of drug in solution (S_T) is equal to $[HA_{(solution)}] + [A^-]$, where $HA_{(solution)}$ is the intrinsic solubility of the drug (S_w). From Eq. 10, the ionized concentration of drug is

$$[A^-] = \frac{K_a[HA]}{[H^+]} \quad (11)$$

giving

$$S_T = S_w + \frac{K_a[HA]}{[H^+]} \quad (12)$$

Since $[HA] = S_w$, $\log K_a = pK_a$ and $\log H^+ = pH$, Eq. 12 can be simplified to,

$$S_T = S_w(1 + 10^{(pH-pK_a)}) \quad (13)$$

which relates the total solubility to the intrinsic solubility and pK_a of the weak monoprotic acid and the pH of the system.

For a weak base in an aqueous solution,

By analogy to the weak acid the total solubility is described by

$$S_T = S_w(1 + 10^{(pK_a-pH)}) \quad (16)$$

where the pK_a refers to HA^+ . Fig. 4 illustrates the general pH-solubility profiles for three solutes having the same intrinsic solubility but different pK_a s.

Fig. 1 illustrates that solubilization by ionization can be very efficient for a mono acidic or basic drug. The linear solubilization slope corresponds to a 10-fold increase in solubility for a one-unit change in pH. Zwitterionic compounds, which have both acidic and basic functional groups, will have a pH solubility plot that will be a combination of those given in the top and bottom portions of Fig. 1. These compounds have a minimum solubility at a pH that is equal to the average of the pK_a s (62–65). The solubilization of divalent acids and bases is similar to their monoprotic counterparts. However, upon the ionization of the second functional group, the solubilization slope is 2 instead of 1, which corresponds to a 100-fold increase in solubility for a one-unit change in pH. A complete mathematical description for the solubilization of a dibasic compound has been given by Garren and Pyter (66).

Fig. 1 (Top) Log solubility, $\log S_T$ vs. pH for typical weak acids having pK_a s of 4, 5, and 6 and the same intrinsic solubility, $\log S_w$. (Bottom) Log solubility, $\log S_T$, vs. pH for typical weak bases (HA^+) having pK_a s of 8, 7, and 6 and the same intrinsic solubility.

Salt Formation

Eqs. 13 and 16 assume that the ionized species of a solute has infinite solubility. However, an ionized solute can form salts with appropriate counterions. The formation of a salt is governed by the solubility product, K_{sp} , of the salt complex. For example, the thermodynamic equilibrium for a chloride salt, BH^+Cl^- , is

where $BH^+Cl^-_{(Solid)}$ represents the solid chloride salt, BH^+ is the ionized base and Cl^- is the chloride counterion. As a result, the concentration of the ionized species will be limited by the solubility of the salt. Some organic salts are very soluble in aqueous systems, others are not and can significantly limit the solubility of a solute. Chowhan (67) demonstrated the effect of four different salts on the pH-solubility profile of naproxen. As shown in Fig. 2, all four salts behave identically between the pH values of 1 and 6, and can be described by Eq. 13. However, depending on

Fig. 2 Solubility-pH profiles, S_T of naproxen and four salts: Δ , potassium salt; \circ , sodium salt; \square , magnesium salt; and ∇ , calcium salt. (From Ref. 67.)

the given salt, the solubility of naproxen is limited at pH values greater than 6.5. The solubilities of the corresponding salts are indicated by plateaus, with the potassium salt having nearly 200 times the solubility of then calcium salt. Hence, at a given plateau the salt is the solid fraction that is in equilibrium with the system, which once again emphasizes the importance of characterizing the solid phase in order to understand what factors are influencing solubility.

Kramer and Flynn (68) have also previously investigated the effect of salt formation on solubility. A graph from their work is given in Fig. 3 and shows the pH-solubility profile for an organic hydrochloride. As can be seen from the data, there is an exponential increase in solubility as would be expected from Eq. 16. The solubility diverges from the expected line and roughly plateaus at pH levels under about 7.2. As pH decreases further, so does solubility, due to the disappearance of the free base from solution after the hydrochloride is formed. Kramer and Flynn illustrated how Eq. 16 can be modified to take into account salt

Fig. 3 Solubility–pH profile of a substituted piperidyl-dioxolane (II) in 0.05 *M* succinate buffer at 30°C. Lines represent theoretical curves. (From Ref. 68.)

formation. Additional mathematical expressions have been developed more recently to characterize pH solubility profiles with the appreciation of counterion affects (69–71).

In addition to overall solubility, salts can have a significant impact on the dissolution rate of a solute. Hence, solubility considerations are important factors to be assessed when trying to make a rational choice of an appropriate pharmaceutical salt (72–77).

Buffers

One practical use of a buffer is to simply maintain the pH of the system over time. For pH solubilized drugs, another practical use of a buffer is to reduce or eliminate the potential for precipitation of the drug upon dilution. It has been shown that drug precipitation upon intravenous injection has been linked to phlebitis (78–82). As shown through the previous discussion, the solubility of a drug can be increased exponentially with pH alteration. However, it also then follows that the solubility can decrease exponentially with pH alteration. If a pH solubilized formulation is diluted with a medium by one half, then the drug concentration will decrease by one half. At the same time the pH of the new mixture may change. If it changes by one pH unit, in a direction that decreases ionization of the drug, then the solubility of that drug will decrease 10-fold. The drug can precipitate if the concentration in the solution exceeds the new solubility.

The degree and extent of precipitation will depend on the ability of a formulation to resist pH change when diluted. The pH change on dilution of one solution by another will depend on the initial pHs and buffer capacities of both solutions. Surakitbanharn et al. (83) illustrated the affect of initial pH and phosphate buffer concentration on pH change when diluted with Sorensen's Phosphate Buffer. Myrdal et al. (82) used the computational model of Surakitbanharn et al. as a means of selecting buffer concentration and initial pH to eliminate the precipitation potential of a weakly basic drug, levemopamil–HCl. Myrdal et al. showed that the unbuffered formulation precipitated upon dilution and resulted in phlebitis *in vivo*, whereas the buffered formulations did not precipitate and did not elicit any phlebitis *in vivo*.

Solubilization through the Use of pH Control

Under the proper conditions, the solubility of an ionizable drug can increase exponentially by adjusting the pH of the solution. From a structural point of view, a drug that can be efficiently solubilized by pH control should be either a weak acid with a low pK_a or a weak base with a high pK_a . Note that the effect of pH on solubilization is independent of the value of the solubility of the unionized form of the drug. In other words the solubility of an unionized acid with a pK_a of 4.2 and a solubility of 1.0 mg/ml and one with the same pK_a and a solubility of 0.001 mg/ml will both be increased by a factor of 1001 at pH 7.4.

Although the use of a buffer will aid in reducing the risk of precipitation upon dilution, there are pH, concentration and buffer type limitations. Physiological compatibility will depend on factors such as the route of administration, tonicity, and contact time. Other factors such as chemical stability as a function of pH must also be considered. Table 4 lists some marketed parenteral products and associated buffers, concentrations and pH values.

COSOLVENTS

A common and effective way by which to increase the solubility of a non polar drug is through the use of cosolvents. A cosolvent system is one in which a water miscible or partially miscible organic solvent is mixed with water to form a modified aqueous solution. Cosolvents have some degree of hydrogen bond donating and or hydrogen bond accepting ability as well as small hydrocarbon regions. The resulting solution will have physical properties that are intermediate to that of the pure

Table 4 Selected list of marketed products that contain buffers

Drug (product)	Route of administration	Buffer, concentration (% w/v) and pH
Methohexital sodium	IV/IV infusion reconstituted	Sodium carbonate pH 9–11
Chlorpromazine–HCl (Thorazine)	IM/IV after dilution	Ascorbic acid 0.2% pH 3.0–5.0
Amikacin sulfate	IM/IV infusion after dilution	Sodium citrate 2.8% pH 3.5–5.5
Biperidan lactate (Akineton)	IV/IM	Sodium lactate 1.4%
Thiopental sodium (Pentothal sodium)	IV infusion reconstituted	Sodium carbonate pH 10–11
Epinephrine–HCL (SusPhrine)	SC	Ascorbic acid 1.0%
Etidocaine HCl (Duranest)	Infiltration	Citric acid pH 3–5
Etoposide (VePesid)	IV infusion	Citric acid 0.2% pH 3–4
Methoxamine HCl (Vasoxyl)	IV/IM	Citric acid 0.3% pH 3–5
Methyldopate HCl (Aldomet ester HCl)	IV infusion after dilution	Sodium citrate 0.3% Citric acid 0.5% pH 3.5–4.2
Nalbuphine HCl (Nubain)	IV/IM/SC	“Citrates” 2% pH 3.5
Perphenazine (Trilafon)	IM/IV/SC	Citric acid pH 4–5.5
Chlordiazepoxide–HCL (Librium)	IM/IV	Maleic acid 1.6% pH 3
Topotecan (Hycamtin)	IV infusion	Tartaric acid 2% pH 2.5–3.5
Diazepam (Valium)	IM/IV	Sodium benzoate/benzoic acid 5.0% pH 6–7
Midazolam–HCL	IM/IV	pH 3
Octreotide acetate 84-(Sandostatin)	SC/IM/IV after dilution	Lactic acid 0.34% pH 4.2
Prochlorperazine edislate (Compazine)	IM/IV/IV infusion after dilution	Sodium biphosphate 0.5%
		Sodium tartrate 1.2% pH 4–6
Phenytoin sodium (Dilantin)	IM/IV	Sodium hydroxide pH 10–12.3

(From Refs. 84–86.)

organic solvent and water through the reduction of water–water interactions. This affords a system that is more favorable for nonpolar solutes.

Table 5 gives some physical properties of commonly used pharmaceutical cosolvents in water. Note that *n*-octanol is added in the table as a reference, since compounds that have large octanol/water partition coefficients have poor aqueous solubility. The use of cosolvent systems that have physical properties that are more similar to those of *n*-octanol would be expected to have greater success in solubilizing a nonpolar drug. In the following section it will be demonstrated that aqueous

solubilization via cosolvency is dependent on both the solute and cosolvent physical properties.

Mathematical Description for Cosolvency

Numerous methods have been proposed to predict or describe the effect of a particular cosolvent system (86–102) on drug solubility. A practical cosolvent model was developed by Yalkowsky and coworkers (103–106) by assuming the mixed solvent system is a linear

Table 5 Physical properties of some common cosolvents and their reference to water and *n*-octanol

Solvent	log $K_{o/w}$	Solubility parameter	Surface tension	Dielectric constant
Water	–4.00	23.4	72.0	81.0
Glycerin	–1.96	16.5	64.9	42.5
Propylene glycol	–0.92	12.6	37.1	32.0
PEG-400	–0.88	11.3	46.0	13.6
Dimethyl sulfoxide	–1.09	12.0	38.0	46.7
Dimethyl acetamide	–0.66	10.8	35.7	37.8
Ethanol	–0.31	12.7	22.2	24.3
<i>n</i> -Octanol	2.94	10.3	20.5	10.3

combination of the pure components. They found that this approach yields the log-linear relationship

$$\log S_{\text{mix}} = \log S_w + \sigma f_c \quad (18)$$

where the logarithm of the solubility of a nonpolar solute S_{mix} will increase with the cosolvent fraction (f_c), having a slope of σ , and an intercept of $\log S_w$. On a linear scale, an exponential increase in solubility is observed with an increase in cosolvent composition. Figure 4 illustrates the linear and exponential solubilization profiles.

For solid solutes, the melting point contributes only to the intercept of the solubilization profile. The independence of the intrinsic solubility and the solubilization slope can be demonstrated by the isomers benzo(a)pyrene and perylene. Figure 5 (top) shows the solubilization of benzo(a)pyrene and perylene in ethanol/water systems.

Fig. 4 Typical cosolvent solubilization curves for a nonpolar drug. (Top) Log-linear scale. (Bottom) Linear scale.

Fig. 5 (Top) Solubilization profile of \blacklozenge , benzo(a)pyrene and \blacksquare , perylene in ethanol–water mixtures. (Bottom) Relative solubilization ($\log(S_{\text{mix}}/S_w)$) of \blacklozenge , benzo(a)pyrene and \blacksquare , perylene in ethanol–water mixtures.

The $\log K_{o/w}$'s (or aqueous activity coefficients) can be considered to be equal for these two compounds, however, their melting points are different. Benzo(a)pyrene has a melting point of 179°C, while perylene has a melting point of 273°C, and as a result, the latter has a lower intrinsic solubility. Yet both compounds have solubilization slopes (σ) which are nearly identical. This is because σ is solely a function of the activity coefficients ($\log K_{o/w}$).

Since the intrinsic solubility does not directly affect the solubilization slope, it is convenient to arrange Eq. 18 to

$$\log(S_{\text{mix}}/S_w) = \sigma f_c \quad (19)$$

By plotting $\log(S_{\text{mix}}/S_w)$ versus f_c , solubilization lines are normalized with respect to the intrinsic solubility and pass through the origin on a semi log plot. This facilitates comparisons among different drugs as well as different cosolvents. Fig. 5 (bottom) shows the solubilization plots of benzo(a)pyrene and perylene using the expression of Eq. 19.

The ability of a cosolvent to solubilize a given solute can be related to the properties of both the solute and cosolvent. The solubilization slope, σ , for a given cosolvent system is dependent upon the polarity of

the drug and the polarity of the cosolvent and can be related by,

$$\sigma = s \log K_{o/w} + t \quad (20)$$

where polarity of the drug is indicated by $\log K_{o/w}$ and the polarity and physical properties of the cosolvent are represented through the parameters s and t .

Dependence of Solubilization on Solute Properties

As illustrated in Fig. 5, isomeric compounds or compounds that have almost identical aqueous activity coefficients (i.e., similar $\log K_{o/w}$'s) will have very similar solubilization slopes for a given cosolvent system. Differences in overall solubility are once again attributed to differences in the crystal contribution to solubility.

For nonpolar solutes, or those solutes that are more nonpolar than the cosolvent of choice, solubilization generally follows the log-linear model of Eq. 18. The degree of solubilization is directly related to the polarity of the solute. From Eq. 20 it has been shown that the solubilization slope, σ , can be related directly to the logarithm of the octanol–water partition coefficient ($\log K_{o/w}$). Fig. 6 shows data for a series of hydrocortisones in propylene glycol. As $\log K_{o/w}$ increases it follows that the solubilization slopes increase. Li and Yalkowsky (107) have also illustrated this relationship for nonpolar solutes in ethanol–water systems. Once again the trend maintains that as $\log K_{o/w}$ increases, solubilization is increased for a given cosolvent system (i.e., s and t are constant). For the

Fig. 6 Solubilization of different hydrocortisones in propylene glycol–water mixtures; ●, hydrocortisone acetate, ◆, hydrocortisone propionate, ×, hydrocortisone butyrate, ▲, hydrocortisone pentanoate, ■, hydrocortisone hexanoate, ○, hydrocortisone heptanoate.

most nonpolar compounds (largest $\log K_{o/w}$'s) solubilization approaches several orders of magnitude.

As $\log K_{o/w}$ decreases so does the ability of an organic cosolvent to solubilize the solute. For solutes that are semipolar and polar (polarities that are between water and a given cosolvent) little gain in solubility, if any, can be expected with the addition of an organic cosolvent. Semipolar solutes will have a maximal solubility at some mixed composition at a polarity that matches the solute. After a maximum solubility the slope becomes negative, and any additional cosolvent will decrease the solubility of the solute. The overall gain in solubility for semipolar solutes is generally less than a factor of five, which is significantly less than that of nonpolar solutes.

The solubility of polar solutes decreases with the addition of an organic cosolvent to water. Although it is obvious that cosolvents would not be used for solubilizing polar solutes, it is important to understand that for formulations that have other components or excipients, the use of a cosolvent for a nonpolar drug may cause solubility problems for polar excipients. If it is a polar drug that is insoluble, a reflection to Eq. 6 will aid in understanding that it is likely the crystal contribution that is limiting the solubility. This is generally the case since polar compounds have significant polar functionalities such as hydrogen bonding moieties that generate a strong crystal structure. If any of the functional groups are acidic or basic, the choice of pH may be the most efficient means by which to solubilize these compounds. Once again the trend maintains that as incremental hydrocarbon groups are added to a base structure, solubilization is increased for a given cosolvent system (i.e., s and t are constant). For the most nonpolar compounds (largest $\log K_{o/w}$) solubilization approaches 5–6 orders of magnitude.

Dependence of Solubilization on Cosolvent Properties

The reduction of intermolecular hydrogen bonding interactions of water when an organic cosolvent is mixed with water creates a solvent system that favors the dissolution of a nonpolar solute. The more nonpolar the cosolvent, the more nonpolar the cosolvent/water system will become and the greater the solubilization of a nonpolar drug. In addition to polarity considerations, it is also useful to take into account hydrogen bond donating and accepting capabilities when evaluating cosolvent systems (108). As can be seen from solubilization of benzocaine with different cosolvent systems in Fig. 7, there is a clear dependence between cosolvent polarity and solubilization. The more nonpolar the cosolvent the greater the solubilization slope.

Fig. 7 Solubilization of benzocaine by *, dimethylacetamide, Δ , PEG-400, \blacksquare , PEG-200, \square , ethanol, \times , methanol, \blacklozenge , propylene glycol; and \circ , glycerin.

Relationship between Solubilization Slope, σ , and Solute Polarity

It is important to recognize that cosolvent solubilization does not rigorously follow a log-linear relationship. In fact a slight negative deviation is observed at low cosolvent compositions and a downward curving positive deviation is often observed at higher cosolvent compositions. Several investigators have attempted to explain or predict this type of behavior (89–102), however, the simplest and most useful remains the log-linear model. Another advantage of the log-linear model is that only two data points are needed to estimate the solubility of a solute in any ethanol–water composition.

With appreciation of the curvature observed for the cosolvent systems given above, a good correlation can still be obtained from simply looking at the terminal slope, σ , of a cosolvent system. That is, by using the log-linear approach (Fig. 4), the slope is simply the difference between the solubility of a solute in the pure cosolvent and in water. The general applicability of this has been demonstrated by Morris et al. (109) and Li and Yalkowsky

Fig. 8 Relationship between solubilization slope, σ and calculated $\log K_{o/w}$ (via $C \log P$) for a variety of different solutes in ethanol cosolvent systems. (From Ref. 107.)

(107). Figure 8 illustrates the relationship between solubilization slope, σ , and $\log K_{o/w}$. The gain in solubilization potential (increase in σ) is directly related to an increase in the calculated $\log K_{o/w}$.

Millard and Yalkowsky (110) have recently evaluated several cosolvent systems using $\log K_{o/w}$'s calculated by CLOGP (15). They found reasonable correlations between the solubilization slope and $\log K_{o/w}$ for ethanol, propylene glycol, polyethylene glycol 400, and glycerol cosolvent systems. A summary of their work is given in Table 6.

From Table 6 it is clear that cosolvent solubilization effectiveness (σ) is directly related to $\log K_{o/w}$. The least polar cosolvent, EtOH, produces the highest σ value, and the most polar cosolvent, glycerol, produces the lowest σ value.

Multiple Cosolvents

The use of multiple cosolvents can be a valuable method for solubilizing a poorly water soluble drug when a dosage form necessitates limits on the amount and type of cosolvent that can be utilized. The effects of multiple cosolvents on solubility can be reasonably approximated

Table 6 Regression analysis of solubilization slope, σ , and $\log K_{o/w}$ (Eq. 20) for different cosolvent systems

Cosolvent	Cosolvent $\log K_{o/w}$	σ	t	n	r^2	SE
Ethanol	−0.31	0.93	0.38	120	0.96	0.53
Propylene glycol	−0.92	0.76	0.57	93	0.93	0.48
Polyethylene glycol 400	−0.88	0.73	1.19	25	0.77	0.62
Glycerol	−1.96	0.34	0.29	26	0.81	0.34

Given are the slope, σ , intercept, t , number of compounds used in the regression, n , and the regression correlation values, r^2 , and standard errors, SE.

by simply expanding Eq. 18 to include a liner addition of cosolvents, i.e.,

$$\log S_{\text{mix}} = \log S_w + \sigma_1 f_{c1} + \sigma_2 f_{c2} + \sigma_3 f_{c3} + \dots \quad (21)$$

where the subscripts 1, 2, and 3 represent the slope and fraction of cosolvents 1, 2, 3, etc. Chien and Lambert (111) found that Eq. 21 adequately represented the solubility of a steroid in mixed solvent systems. Similarly, Prammar and Das Gupta (112) found that the solubility of spironolactone (Fig. 9) in multiple cosolvent systems followed a log-linear relationship. Data from Prammar and Das Gupta are presented in Fig. 10, showing the solubility of spironolactone for some ternary systems. Figure 10 demonstrates a nearly linear increase in solubility of spironolactone as the amount of propylene glycol or glycerin is added to a given PEG-400 concentration. All of the systems include 10% ethanol, giving a ternary system. Further investigation of the data, reveal that propylene glycol is a more efficient solubilizing agent than glycerol. In fact, the slope for propylene glycol is nearly twice that of glycerol, which is very similar to the findings above for the single cosolvent systems (Table 8).

Eq. 21 assumes that each cosolvent interacts independently. Of course this is not always the case. In fact the data of Prammar and Das Gupta (112) show a synergistic affect for the solubilization of the nonpolar solute, spironolactone. In addition, the use of one cosolvent can be used to increase the solubility of a partially miscible cosolvent in water. The facilitated cosolvency effect of multiple species in water has been shown by Gupta et al. (113) and Riley (114).

Solubilization through the Use of Cosolvents

Cosolvents can be a powerful tool by which to solubilize drugs. For a given cosolvent selected, it is clear that the degree of solubilization attained for any solute is directly proportional to the octanol/water partition coefficient of

Fig. 9 Structure of spironolactone.

Fig. 10 Ternary cosolvent systems and resulting solubilization of spironolactone. S_0 represents the solubility of spironolactone in a 10% ethanol/water system. Given in the figure are different concentrations of PEG-400 with varied propylene glycol or glycerin volume fractions. (From Ref. 112.)

that solute. However, as with pH solubilization, solubilization through cosolvents is logarithmic, and as a result there is the potential for precipitation upon dilution.

A potential limitation to the use of cosolvents may be the choice and amount of cosolvent needed. For pharmaceuticals there are relatively few organic cosolvents that are generally regarded as safe. Rubino (115) has discussed the biological effects of many of the commonly utilized cosolvents such as ethanol, propylene glycol, glycerol, polyethylene glycols, and dimethylacetamide (DMA). The permissible amount of a given cosolvent will be dependent upon the dosage form. Table 7 gives some examples of products that contain cosolvents. The introduction of new, safe cosolvents would greatly enhance the technique of using cosolvents for solubilization. However, even with the limited number of acceptable cosolvents, cosolvency is clearly a valuable methods by which to solubilize poorly water soluble drugs.

SURFACTANTS

Surfactants are molecules with distinct polar and nonpolar regions. Most surfactants consist of a hydrocarbon segment (usually in the form of a long aliphatic chain segment) connected to a polar group. The polar group can be anionic (such as a carboxylate, sulfate, or sulfonate), cationic such as ammonium, trialkylammonium, or pyridinium), zwitterionic (such as glycine or carnitine) or nonionic such as polyethylene glycol, glycerol, or sugar. An illustration of the general structure of classical surfactants, as well as different pictorial representations, are illustrated in Fig. 11. Selected structures of non-classical surfactants are illustrated in Fig. 12. Although

Drug (product)	Route of administration	Cosolvent composition (% w/v)

Fig. 12 Structure for the nonclassical surfactants cholic acid and generic structural features for polysorbates and poloxamers.

representation for a solute's total solubility, S_T , in a surfactant system is

$$S_T = S_w + \kappa(C_{\text{surf}} - \text{CMC}) \quad (22)$$

where C_{surf} is the total concentration of the surfactant and κ is the solubilization capacity. The quantity in parenthesis in Eq. 22 represents the micelle concentration. The solubilization capacity reflects the number of surfactant molecules that are required to solubilize a single solute molecule. Deviations from Eq. 22 are usually the result of changes in micelle shape or size that occur as the concentration of surfactant increases.

A micelle is a dynamic aggregation of any number of individual surfactant molecules, or monomers. Although the molecules are intertwined, they are in constant motion like those of a liquid. Thus, the interior of a micelle can be thought of as a separate phase and a micellar solution can be thought of as a microdispersion of that phase in water. If the micelle is considered to be a separate phase, it is then convenient to evaluate the solubilization capacity (κ), in terms of the partition between the micelle and water. The micellar partition coefficient, K_m , is defined as the ratio of the solute concentration in the micelle, C_m , to that of water, C_w :

$$K_m = C_m / C_w \quad (23)$$

The micelle/water partition coefficient for many solutes have been shown to correlate to the octanol/water partition

Fig. 13 Illustration of a micellar structure with nonpolar solutes in the core of the micelle.

coefficient (116–121). Data in Table 8, from Azaz and Donbrow (116), show that the micellar partition coefficients of the methylphenols increase with the number of methyl groups. Collett and Tobin (119) showed that the micellar partition coefficients of several benzoic acid derivatives are proportional to their octanol–water partition coefficient for poloxamers (Table 9). Tomida et al. (119) also illustrated that most of the 34 monosubstituted benzoic acids with Brij 35 have micellar partition coefficients that are inversely proportional to their aqueous solubilities and proportional to their octanol–water partition coefficients. The data of Tomida et al. (121) for some steroid hormones (Table 10), further illustrate the parallelism between octanol–water and micelle–water partition coefficients.

(From Ref. 116.)

Semipolar solutes are generally solubilized by the polar regions of nonionic surfactants. The solute is absorbed into the polyoxyethylene mantle rather than the hydrocarbon core. The micellar partition coefficients of the semipolar solutes is also dependent upon their octanol–water partition coefficient. However, since these solutes are solubilized primarily in the mantle, the surfactant property that is most important is the number of polyoxyethylene units, and the alkyl chain length of the surfactant plays only a minor role in determining the micellar partition coefficient of a semipolar solute.

Materials that are solubilized in polyethylene glycol can be solubilized in the polyoxyethylene chains on the surface of a nonionic micelle. Ismail et al. (122) found that the micellar partition coefficients of barbiturates in polysorbates 20, 40, 60, and 80 is a function of the solute substituents and is proportional to the octanol–water partition coefficient of the barbiturate. Similarly, Ikeda

(Based on Ref. 121.)

et al. (123) showed that the solubilization of alkyl barbiturates by polyoxyethylene lauryl ether is not dependent upon the number of carbons in the substituents. Since the different polysorbates contain different aliphatic groups, the rather small dependence of solubilization upon polysorbate number (i.e., upon alkyl chain length) suggests that the barbiturates are not solubilized primarily in the hydrocarbon portion of the micelle. Gouda et al. (124) showed that the solubilization of barbiturates in polyoxyethylene stearates is proportional to the number of polyoxyethylene units in the surfactant.

Jafvert et al. (125) developed the following equation for predicting the molar solubilization capacity of organic

Table 9 Micellar partition coefficients of some benzoic acid derivatives by poloxamer L64 at 37°C

(From Ref. 119.)

compounds in nonionic surfactants on the basis of surfactant structure as well as solute structure.

$$K_M = K_{o/w}(0.030\sim L_1 - 0.0058\sim L_2 - 0.0056\sim L_3 + 0.0319\sim L_4) \quad (24)$$

where:

L_1 = number of straight chain aliphatic carbons in the hydrophobic tail

L_2 = number of repeating ethoxy groups

L_3 = number of carbons in a sorbitan group

L_4 = number of total carbons in alkylbenzene groups

This equation relates the micellar partition coefficient to the octanol–water partition coefficient. It also accounts for both the polar and nonpolar surfactant moieties.

Alvarez-Nunez and Yalkowsky (126) showed that the molar micellar partition coefficient is related to the octanol–water partition coefficient for a structurally diverse set of pharmaceutically important compounds through the relationship

$$K_M = a \log K_{o/w} + b \quad (25)$$

Which for posysorbate 80 is equal to

$$K_M = 0.92 \log K_{o/w} - 0.07 \quad (26)$$

Eq. 26 is then used to estimate total solubility by the equation

$$S_{\text{tot}} = S_w [1 + C_{\text{polysorbate}} \times 10^{(0.92 \log K_{o/w} - 0.07)}] \quad (27)$$

where $C_{\text{polysorbate 80}}$ is the concentration of polysorbate 80.

While both Eqs. 24 and 26 are quite useful, they must be employed with caution, especially for solutes that have some degree of amphiphilic character. Solutes that have surface-active physicochemical properties themselves (i.e., they have separate polar and nonpolar regions) tend to be more soluble than expected because they can accumulate at the core/mantel interface or the core/water

interface. In essence, weakly amphiphilic solutes can act as cosurfactants and form mixed micelles with nonionic surfactants as well as with ionic surfactants. This can alter both the CMC and the size of the micelle. In most cases this leads to a higher degree of solubilization than would be predicted on the basis of either molecular size or partition coefficient.

In summary, micellar solubilization for both nonpolar and semipolar surfactants can be obtained. Due to the limitation on surfactant quantity that can be practically used, due to biological constraints, micellar solubilization is typically more advantageous for low dose formulations. In addition, although a large number of anionic, cationic and nonionic surfactants are available for use as solubilizing agents (128–131), only polysorbate-80 and cremophor EL have been used to any significant extent in parenteral products. Table 11 lists some parenteral formulations that contain surfactants. It should be noted that adverse clinical events have been observed for patients receiving cremophor EL.

COMPLEXATION

Complexation is the association between two or more molecules to form a nonbonded entity with a well-defined stoichiometry. The two types of complexation that are most useful for increasing the solubility of drugs in aqueous media are stacking and inclusion. Stacking complexes are formed by the overlap of the planar regions of aromatic molecules, while inclusion complexes are formed by the insertion of the nonpolar region of one molecule into the cavity of another molecule (or group of molecules).

The mathematical description for the equilibrium constant of a 1:1 complex, $K_{1:1}$, is defined by

$$K_{1:1} = [SL]/[S][L] \quad (28)$$

Table 11 Examples of some products that contain surfactants

Drug (Product)	Route of administration	Surfactant composition (% w/v)
Taxol (Paclitaxel)	IV infusion after dilution	51% Cremophor EL
Valrubicin (Valstar)	IV infusion after dilution	50% Cremophor EL
Chlordiazepoxide HCl (Librium)	IM/IV (diluent)	4% Polysorbate 80

Amiodarone (Cordarone)	IV infusion after dilution	10% Polysorbate 80

(From Refs. 84–86.)

where S is the concentration of the free solute, L is the concentration of the free ligand, and $[SL]$ is the concentration of the solute/ligand complex. The equilibrium constant is also commonly referred to as the stability constant or the complexation constant. If it takes two ligand molecules to complex with a solute molecule the complexation constant is defined by

$$K_{1:2} = [SL_2]/[S][L]^2 \quad (29)$$

The total solubility of the solute, S_T , for a solute that forms a 1:1 complex is

$$S_T = S_w + [SL] \quad (30)$$

where S_w is the intrinsic solubility of the solute in water. Similarly the total concentration of ligand, $[L^{tot}]$, in the system is

$$[L^{tot}] = [L] + [SL] \quad (31)$$

Combining Eqs. 28, 30, and 31, gives the general equation for solubilization by 1:1 complexation,

$$S_T = S_w + [K_{1:1}S_w/(1 + K_{1:1}S_w)]L^{tot} \quad (32)$$

where the intercept is the aqueous solubility of the solute. Eq. 32 represents a linear increase in the solubility of the solute with increasing ligand concentration, with a slope, $\sigma_{complex}$, of

$$\sigma_{complex} = [K_{1:1}S_w/(1 + K_{1:1}S_w)] \quad (33)$$

and the stability constant is

$$K_{1:1} = \sigma_{complex}/[S_w(1 - \sigma_{complex})]. \quad (34)$$

From the above it can be seen that, as the stability constant of a 1:1 complex increases, the slope will increase until the value converges to unity for a strong complex in which one ligand molecule solubilizes one solute molecule. The initial segment of the curve in Fig. 15 illustrates this. This linear region will continue until the solubility of the complex itself is reached, at which point the total solubility of the solute remains constant, as indicated by the central segment of the curve. A plateau is analogous to the maximum solubility of a salt as described previously. Further addition of the complexing agent can result in a reduction in of the concentration of the free solute and a leveling off of the curve at the solubility of the pure complex as illustrated by the final segment of the curve in Fig. 15.

The solubilization curve for a solute molecule that complexes with two ligand molecules is more complicated than those shown in Fig. 15. If the complexation constant for a second ligand is significantly lower than the first, a 1:1 complex will be formed at lower ligand concentration.

Fig. 15 General solubilization profile for complexation.

It will then combine with a second ligand to produce a 2:1 complex. Assuming that the latter is more soluble than the 1:1 complex, the solubilization curve will have two distinct slopes. If each ligand is equally capable of complexing with the solute, they will complex simultaneously to produce a convex up solubilization curve.

According to Eq. 32, the factors that determine the degree of solubilization of the solute are the complexation constant and the solubilities of the solute, the ligand, and the complex. As a result, the most useful ligands for solubilization in aqueous media are highly water soluble, and produce soluble complexes.

Self-Association and Stacking Complexation

Nonpolar moieties tend to be squeezed out of water by the strong hydrogen bonding interactions of the water. This causes some molecules to minimize the contact with water by aggregation of their hydrocarbon moieties. This aggregation is favored by large planar nonpolar regions in the molecule. Just as micelles can be pure or mixed, stacked complexes can be homogenous or mixed. The former is known as self-association and the latter as complexation. Some examples of substances that interact in an aqueous media by stacking are shown in Fig. 16.

Higuchi and Kristiansen (132) found that complexes formed between compounds containing aromatic acids or amides and compounds with aromatic nitrogens, such as those depicted in the second and third row of Fig. 16, consistently had higher stability constants than complexes made of a single compound. There have been a number of attempts to quantitatively relate or classify the chemical structures of the solute and ligand with their ability to complex (132–137).

Fig. 16 Some compounds that are known to form stacking complexes.

Inclusion Complexes

An inclusion complex is produced by the inclusion of a nonpolar molecule or the nonpolar region of a molecule (known as the guest) into the nonpolar cavity of another molecule or group of molecules (known as the host). When the guest molecule enters the host molecule the contact between water and the nonpolar regions of both is reduced. Thus, inclusion phenomena are the result of the same driving force that produces micellization, self-association, and stacking; namely the squeezing out from water of nonpolar moieties.

The major structural requirement for inclusion complexation is a snug fit of the guest into the host cavity. The host cavity must be large enough to accommodate the guest and small enough to eliminate water so that the total contact between water and the nonpolar regions of the host and the guest is reduced.

The most commonly used host molecules are the cyclodextrins. These cyclic oligomers of glucose are relatively soluble in water and have cavities large enough to accept nonpolar portions of common drug molecules. The naturally occurring cyclodextrins contain 6, 7, and 8 glucopyranose units and are termed α , β , and γ ,

respectively. These are represented in Fig. 17 where “G” represents a glucopyranose unit. Modified cyclodextrins have one or more of the hydroxy groups of one or more of the glucopyranose units modified. Some of the more common modifications are with alkyl or hydroxyalkyl groups, or with anionic or cationic functionalities. Many of these modified cyclodextrins are more soluble than their naturally occurring precursors (138–140).

The size of the cavity in the cyclodextrin is the major factor in determining which guest solutes will be most acceptable for complexation. In general, alkyl groups will

Fig. 17 Schematic representation of two views of the naturally occurring α , β , γ cyclodextrins.

Fig. 18 Representation of the incorporation of pentane, benzene, and pyrene into α , β , and γ cyclodextrins.

fit well into the cavity of the α -cyclodextrins. The β -cyclodextrins are most well suited for accepting single aromatic rings, and the γ -cyclodextrins have large enough cavities to accommodate larger hydrocarbons such as pyrene. Fig. 18 illustrates these as well as other representative inclusion complexes.

The degree to which a solute molecule will be solubilized by a cyclodextrin molecule will depend on several properties. First the solute molecule must have a significant nonpolar portion in order to be squeezed out of the water and into the cyclodextrin cavity. Since the interior dimensions of a given cyclodextrin are fixed, a significant part of the molecule (or whole molecule) must then fit inside the cyclodextrin. Once presented to the interior cavity, it will be the fit, as well as the intermolecular interactions between the two molecules that will determine the strength of the complex. The stability constants for some compounds are given in Table 12. Note that the compounds in the upper third of the table contain aliphatic chains and are preferentially solubilized by α -cyclodextrin, while those in the middle contain aromatic rings and are best solubilized by β -cyclodextrin. The bottom third of the table contains fused ring compounds that are best solubilized by the larger γ -cyclodextrin.

Seo et al. (141) have shown the dependence of stability constant and overall solubility upon cyclodextrin ring size for spironolactone. From the data given in Fig. 19, it can be

(Based upon Ref. 1.)

seen that for the relatively large spironolactone molecule (Fig. 9) the stability constant increases with size of the host cavity that is reflected through an increase in the linear slopes. The lowest maximum solubility was obtained with the β -cyclodextrin, which has the lowest solubility of the three cyclodextrins (142).

As discussed earlier and shown in Fig. 19, a significant limitation to the naturally occurring cyclodextrins is their limited solubility. Based on this and other physical property limitations, numerous derivatives have been prepared from the base cyclodextrins (143–147). Among the most studied of these is that of the hydroxypropyl- β -cyclodextrin, HP- β -CD and the sulfobutylethers of β -cyclodextrin, SBE- β -CD. These compounds are very soluble in water and can be used in high concentrations. Pitha et al. (148) investigated the use of high concentrations of HP- β -CD for a variety of compounds and found a wide range of solubility enhancement. The data from Pitha et al. is given in Table 13. SBE- β -CDs, have also shown good complexation characteristics. Table 14 shows the solubility enhancement for some selected compounds in a solution of Sulfobutylether

Fig. 19 Solubility of spironolactone as a function of cyclodextrin and concentration. ○, α-cyclodextrin, □, β-cyclodextrin, and, △, γ-cyclodextrin. (From Ref. 14.)

β-cyclodextrin IV. The selected data given in Tables 13 and 14 provide a good illustration of the practical range of solubilization that can be achieved by complexation.

Combination of pH and Complexation

The effect of pH on solubilization by complexation will depend entirely on the given solute and ligand. Tinwalla et al. (150) found that the combined use of ionization and complexation can be a powerful method for solubilization. They were able to significantly increase the solubility for a

thiazolobenzimidazole derivative, TBI (shown in Fig. 20), through the use of both pH and complexation via HP-β-CD.

Li et al. (151, 152) derived a mathematical expression to explain the combined effect of pH and complexation on solubilization. If either the ligand or solute ionizes with pH, the stability constant will typically decrease. However, even with a decrease in the stability constant the solubility can sometimes increase. Although the

Fig. 20 Solubility of TBI (structure top, $pK_a = 3.55$), as a function of pH for 0 and 40% HP-β-CD solutions. (From Ref. 150.)

Table 15 Examples of some parenteral products that contain complexation agents

Drug (Product)	Route of administration	Surfactant composition (% w/v)

(From Refs. 84–86.)

stability complex for the protonated form of TBI was nearly 13-fold less than that of the neutral complex, they were still able to attain a 3-fold increase in solubility.

Solubilization through Complexation

With the general characterization for stacking complexes being planar, the list of possible candidates is extensive. Of course, not all possible ligands can be considered acceptable. Some of the planar molecules that form stacking complexes (such as those given in Fig. 16) are pharmacologically active. Others like the parabens or benzyl alcohol can be used as antimicrobial agents. Furthermore, the addition of these organic compounds can also facilitate solubilization through cosolvency. Inclusion complexation has been proven to be useful for compounds with isolated hydrocarbon regions. Solutes with large or multiple hydrocarbon regions are most efficiently solubilized by complexation, however a shape requirement must be met in order for inclusion complexation to occur. An abbreviated list of excipients used in some parenteral products is given in Table 15.

SPECTROSCOPIC METHODS OF ANALYSIS—ATOMIC ABSORPTION AND EMISSION SPECTROPHOTOMETRY

John P. Oberdier

Abbott Laboratories, Abbott Park, Illinois, U.S.A.

INTRODUCTION

Often it is necessary to measure the metal content of different kinds of samples in the pharmaceutical industry. These samples can be actual products that have metals, such as calcium or magnesium added for their therapeutic value or biological samples, such as blood, urine, and tissue. More recently, work has been done on the role of metals in biological processes. In addition, products can be monitored for trace metal contamination, that can lead to unexpected degradation of product. A number of techniques are available for metal analyses. Some of the more common techniques are colorimetry, titrimetry, atomic absorption spectrophotometry (AA), fluorescence spectrophotometry, and emission spectrophotometry. The most common form of emission spectrophotometry is inductively coupled plasma (ICP). Thus, the analyst must choose the best approach for the sample being analyzed. The purpose of this article is to give a general overview of the strengths and limitations of atomic absorption spectrophotometry and ICP so that the best technique can be selected for the problem to be solved.

PRINCIPLE OF OPERATION FOR ATOMIC ABSORPTION SPECTROPHOTOMETRY (1)

The basis of atomic absorption spectrophotometry is the absorbance of light by the free, ground-state atoms of the element of interest. The ground state of an atom is the electronic state in which all the electrons are in their most stable configuration or orbitals. When light is absorbed by an atom, one or more of the electrons is excited to a higher energy orbital. The word free refers to the lack of any effects that would alter the amount of energy or the wavelength of the energy that is needed to cause the electrons in the atoms to shift from the ground state to an excited state(s).

Because each element absorbs at very discrete wavelengths, the lamp used for analysis of a particular metal emits light only at the desired wavelengths and is

specific for that element. The two kinds of lamps used in atomic absorption spectrophotometry are the hollow cathode lamp (HCL) and the electrodeless discharge lamp (EDL). These lamps contain a deposit of the metal of interest in an inert gas atmosphere and then use either a charged anode/cathode or a radio frequency to excite the metal atoms. As the excited atoms relax, they emit the absorbed energy as light energy at the characteristic wavelength(s) for that particular metal. This light energy is focused through the sample chamber onto the monochromator and detector as shown in Fig. 1.

The concentration of the analyte in the sample chamber is proportional to the amount of light absorbed and, under the proper experimental conditions, follows Beer's law. This relationship is defined as $A = abc$, where A is the absorbance, a is the absorption coefficient of the analyte, b is the cell path length, and c is the concentration of the analyte. The concentration of unknown samples can be readily determined by comparing the absorbance of a sample of known concentration(s) with the absorbance of the test sample.

SAMPLE INTRODUCTION TECHNIQUES AVAILABLE FOR ATOMIC ABSORPTION SPECTROPHOTOMETRY

One limitation of atomic absorption spectrophotometry is that the samples generally have to be in solution, preferably aqueous. Thus, either the sample must be directly soluble in a suitable solvent or some type of pretreatment, such as acid digestion, is necessary. One exception is that some instruments using a graphite furnace can be modified for direct injection of solids. Another limitation is that only one metal can be analyzed at a time. There are four primary methods of accomplishing this:

1. flame (aspiration of sample solution);
2. cold vapor (or chemical vaporization);
3. hydride generation (or chemical vaporization); and
4. Graphite furnace (or electrothermal atomization).

Fig. 1 Comparison of major components of atomic absorption and (A) emission spectrophotometers (B). (Courtesy of Perkin-Elmer Instruments).

All these methods have one common goal; to get the analyte atoms into the light path as free, ground-state atoms. Thus, there must be a balance of supplying enough energy so that the analyte atoms are free from association with other atoms (or molecules) in the sample matrix, versus not having excess energy, thereby allowing the electrons of the analyte atoms to remain in the ground state.

The technique of flame atomic absorption spectrophotometry accomplishes this by aspirating the sample solution into a burner chamber, where it is mixed with a fuel gas and an oxidant gas. The mixture is then burned in a specially designed burner head (Fig. 2). The light beam is directed lengthway down the burner, and the absorption of the analyte atoms in the flame is measured. The most commonly used gas mixtures are air with acetylene and nitrous oxide with acetylene. Experimental conditions are

well-defined in the literature, and “cookbook” conditions are available from most instrument manufacturers. In addition, many instruments are computer-controlled, and typical conditions are available directly on the operating screen. Figure 3 shows the type of information usually available. These conditions provide excellent starting points for new methods, and in many cases the manufacturers provide information on possible interferences and the linear range for each element.

Table 1 shows the detection limits of atomic absorption spectrophotometry for various metals. In general, flame atomic absorption spectrophotometry is quantitative in the lower parts-per-million levels and is readily automated for routine, high-volume samples. The other three techniques are used primarily for trace analysis and are quantitative to the lower parts-per-million levels for many elements.

Data Remarks

Fig. 3 Typical operation screen for copper using flame atomic absorption spectrophotometry (Courtesy of Perkin-Elmer Instruments.)

The cold vapor technique is used for mercury. This technique involves reducing the mercury to the zero valence state with either sodium borohydride or stannous chloride. The mercury is then swept into a gas cell aligned in the light path of the spectrophotometer, using a stream of nitrogen or air. Fig. 4 shows a diagram of a typical unit.

A broad peak is obtained on the graph. Either the peak height or the integrated peak area is measured and compared with that obtained for a specific volume of a known concentration. Note that this technique measures the total mercury present in the sample aliquot. Thus, both the mercury concentration and the sample volume analyzed are important in determining the sensitivity of the assay. Generally, the sample volume is less than 50 ml; however, volumes up to 100 ml have been used. One potential problem with this technique is that the mercury must be in a form that is easily reduced. If there are complexing agents or organo mercury compounds that do not yield Hg atoms, these compounds must be treated before analysis. Frequently, acid digestion of the sample before analysis brings the sample to the desired state for analysis.

The technique of hydride generation is very similar to the cold vapor technique addressed previously. Seven metals (arsenic, bismuth, germanium, antimony, selenium, tin, tellurium) can be analyzed using this method. First, the volatile hydrides are formed by reacting the sample with sodium borohydride. The metal hydride is then swept into a heated gas cell using a stream of argon. Anything in the sample matrix that prevents the metal hydride from forming easily causes an interference. However, this technique is applicable to many complicated samples that

are very difficult or impossible to analyze using other techniques.

The final technique described for atomic absorption spectrophotometry is the graphite furnace. In this technique, a tubular, high-temperature furnace is placed in the light path of the spectrophotometer so that the light is focused down the center of the sample tube. The sample tube is a hollow cylindrical tube made of compressed graphite, with or without a pyrolytic graphite coating. The tube may also be equipped with a L'vov platform. One of the primary advances of this technique have been in furnace and sample tube design to improve the uniformity of heating. Uneven heating causes reproducibility problems and spattering or loss of sample. An atmosphere of inert gas is maintained in the sample chamber to prevent oxidation of the graphite tube during the subsequent heating steps. Typically 5–50 μ l of the sample are deposited on the bottom side of the tube or on the L'vov platform, and the tube is electrically heated to evaporate the sample solvent (100–200°C). If the sample contains organic material, the sample is usually ashed (600–1000°C). After this step, the inert gas flow is interrupted, and the metal is volatilized (1500–3000°C) and then measured. Matrix modifiers may be added to the sample to prevent loss of the analyte, before the volatilization step. All of these parameters are set up and optimized during initial method development. The preliminary settings are readily available in the literature and from most instrument manufacturers. Once the conditions have been chosen, the entire sequence can be automated, including use of an autosampler. An autosampler is especially recommended for this technique because one of the primary causes of irreproducibility is improper or inconsistent placement of the sample in the sample tube. Many autosamplers will add matrix modifiers and/or known amounts of standards to samples for standard addition-recovery experiments.

One of the inherent problems in the graphite furnace technique is background correction. When the metal atoms are volatilized, there may be absorption or loss of light that is not related to the metal atom concentration. For example, there may be small amounts of partially carbonized material that also volatilizes and causes light scattering. There are at least two methods available to correct for background effects: continuum correction and Zeeman correction. Continuum background correction assumes that absorption or loss of light, caused by effects other than atomic absorption, are constant over the entire spectral range. Thus, the sample signal is corrected by electronically subtracting the background absorption at a wavelength where the metal being measured does not absorb. This technique works well for background effects

^a Denotes that the ICP-MS detection limit was measured under cold plasma conditions.

All detection limits are given in micrograms per liter and were determined using elemental standards in dilute aqueous solution. All detection limits are based on a 98% confidence level (3 S.D.). All atomic absorption (Model 5100) detection limits were determined using instrumental parameters optimized for the individual element, including the use of system 2 electrodeless discharge lamps where available. ICP emission (Optima 3000) detection limits were obtained under simultaneous multielement conditions with a radial plasma. Detection limits using an axial plasma (Optima 3000 XL) are typically improved by 5–10 times.

Cold vapor mercury detection limits were determined with a FIASTM-100 or FIAS-400 flow-injection system with amalgamation accessory. The detection limit without an amalgamation accessory is 0.2 µg/L with a hollow cathode lamp, 0.05 µg/L with a System 2 electrodeless discharge lamp. (The Hg detection limit with the dedicated FIMSTM-100 or FIMS-400 mercury analyzers is <0.010 µg/L without an amalgamation accessory and <0.001 µg/L with an amalgamation accessory.) Hydride detection limits shown were determined using an MHS-10 Mercury/Hydride system. Graphite furnace AA detection limits were determined using 50-µl sample volumes, a L'vov platform, and full STPF conditions (Model 5100 PC with 5100 ZL Zeeman Furnace Module or Model 4110 ZL). SIMAA 6000 detection limits are similar in its multisource and are typically two to five times better in its single-source mode. Graphite furnace detection limits can be enhanced further by the use of replicate injections.

ICP-MS detection limits were determined using a 3-S integration.

Fig. 4 Diagram of a typical unit for vapor or hydride generation technique. (Courtesy of Perkin-Elmer Instruments.)

such as light scattering that are fairly continuous over the entire spectral range. However, many background effects are not continuous, and the analyte signal is either under- or overcorrected. Zeeman background correction relies on the Zeeman effect. In simplest terms, Professor Zeeman discovered in 1896 that when an atomic line spectrum was subjected to a magnetic field, the lines were split into multiple components. Thus, the corrected sample signal can be obtained by electronically subtracting the sample absorbance in the presence and absence of a magnetic field. Because the background is actually being measured at the analyte wavelength, the measurement is generally less susceptible to error.

COMMON SOURCES OF ANALYTICAL ERROR IN ATOMIC ABSORPTION SPECTROPHOTOMETRY

The two common sources of analytical error are interference during the analytical measurement and contamination during sample preparation. During

the analytical measurement, potential interferences include, matrix effects: chemical interferences, ionization interferences, and spectral interferences.

Matrix effects usually involve physical parameters, which differ between samples and standards. For example, in flame atomic absorption spectrophotometry, if the viscosity of the sample and standard solutions is significantly different, the solutions are aspirated into the burner chamber at different rates and the responses are different. Viscosity effects can often be eliminated by adding 1–2% of a metallic salt to the analyte solutions. Chemical interference can include both complexes and organically bound metals. When these type of interference are encountered, the samples often have to be digested with acid to destroy the organic material. For chemical complexes, adding a large excess of a competing ion is an alternative to acid digestion. Ionization interference is very common for sodium, potassium, and lithium. To overcome this problem, a large excess of one of the other elements is added. For example, 1–2% lithium might be added to a sample being analyzed for potassium. Ionized potassium atoms can collide with the large excess of lithium atoms, resulting in the loss of energy for the potassium atoms. These atoms will return to the ground state

and be measured. Finally, there may be spectroscopic interference such as molecular or atomic absorption at the analyte wavelength. In practice, this interference can normally be overcome, and very complex samples can be analyzed rapidly and accurately, provided the analyst recognizes the potential interference and takes appropriate steps to minimize it.

Contamination during sample preparation is probably the single major source of error in this technique and is especially important when analyzing for metals at the parts-per-million level. Contamination can occur because of improperly cleaned containers or the wrong type of container (such as glass versus plastic). In addition, contamination can come from reagents used to prepare the sample. Special grade acids or matrix modifiers are usually necessary for trace metal analysis. Another source of contamination is the general environment. For example, even a dust particle can cause errors of 10-fold or more in the analysis of aluminum. In summary, serious thought must be given to every material and reagent the sample will contact during the entire sample-handling process. A series of review articles (2–6) are listed in the references for additional reading on atomic absorption spectrophotometry.

PRINCIPLE OF OPERATION AND TECHNIQUES USED IN EMISSION SPECTROPHOTOMETRY (7)

Emission Spectrophotometry is a complementary technique to atomic absorption. In this technique, the electrons in the atoms are excited by electrical or thermal energy to an unstable energy state. When the atom returns to a more stable state or the ground state, energy as light is emitted. This emitted light is detected and quantitated in emission spectrophotometry. The wavelength(s) of the emitted light is specific to the element(s) that are present. Figure 1 compares the major components of atomic absorption and emission spectrophotometry.

This emission of light from elements was reported as early as the mid-1700s and was later the basis of discovering four elements by Kirchoff and Bunsen in the mid-1800s. However, it was not until the 20th century that the technique really became a useful analytical tool. The first analytical instruments used a spark discharge to provide the energy to excite the atoms so that they would emit light. This approach gave valuable qualitative and semiquantitative information but did not have the accuracy and precision needed for many applications. The one exception was the analysis of alkali earth metals, which require very little energy to raise the electrons to an

excited state. A simple propane flame is sufficient. This led to the development of a clinical analyzer for sodium and potassium in blood and urine samples that is still used routinely in clinical laboratories. It was not until the argon plasma flame was developed that a reliable source of high energy was available to excite a wide variety of atoms so that they would emit light. This led to the development of the technique commonly referred to as inductively coupled plasma (ICP) spectrophotometry.

As noted previously, the argon plasma flame provided the reliable energy source needed for ICP to become a reality. The plasma is created by passing argon gas between two concentric quartz tubes while applying an RF field (Fig. 5). This plasma flame reaches temperatures up to 10,000°K, with the sample reaching temperatures of 5500–8000°K. The shape of the flame confines the sample emission to an optically thin source resulting in a wide dynamic range for ICP. The sample is aspirated into the argon plasma flame, where it is believed to go through several steps: desolvation, vaporization, atomization, and finally excitation or ionization. As the different atoms relax to a lower energy state, the emitted light strikes a monochromator or polychromator, and the intensity of the line spectra for each element is measured at the appropriate wavelength(s) for that element.

Fig. 5 Cross section of an ICP torch and load coil depicting an ignition sequence. (A) Argon gas is swirled through the torch; (B) RF power is applied to the load coil; (C) a spark produces some free electrons in the argon; (D) the free electrons are accelerated by the RF fields, causing further ionization and forming a plasma; (E) the sample aerosol-carrying nebulizer flow punches a hole in the plasma. (Courtesy of Perkin-Elmer Instruments.)

The most commonly used technique of sample introduction is aspiration of the solution into the argon plasma flame. Because of the high temperatures in the flame, many of the problems associated with atomic absorption are eliminated. However, matrix effects such as significant differences in viscosity between sample and standard solutions can still have an effect. When needed, most of the techniques of sample introduction used in atomic absorption spectrophotometry can also be used for sample introduction in emission spectrophotometry [see the review articles (8–13) listed in the references].

HOW TO CHOOSE AMONG THE TECHNIQUES

The major advantage of ICP is that multiple elements can be analyzed at the same time. The rule of thumb is if one typically assays less than four to six metals in a sample, atomic absorption is the better route. However, for more than six metals, ICP is clearly the choice. However, other factors such as sensitivity and interferences also have to be considered. One other variation of ICP that is becoming important is the hyphenated technique of ICP–MS (mass spectrophotometry). This combination gives excellent sensitivity and can even differentiate ionic species or isotopes if needed. Table 1 summarizes the sensitivities of the various techniques. As noted previously, all these techniques are complimentary, and the various strengths and weaknesses must be understood to choose the best technique.

THE FUTURE

The instrumentation for atomic absorption spectrophotometry is very well-defined and can range from a relatively simple manually operated instrument to a completely automated system that is on line to a central database. In addition, accurate results can be obtained on a wide range of samples. The future lies in using this technique to solve problems rather than to further develop instrumentation. For example, the FDA published new guidelines for the aluminum content of products used in total parenteral nutrition.

The role of ICP in the future will continue to expand, especially with the development of ICP–MS. The role of metals in biological processes and disease states is just beginning to be understood, with numerous studies being published. For multivalent metals, the exact species of metal involved in the biological process can be determined with ICP–MS. Understanding this type of detail will

hopefully lead to important breakthroughs in the future. See the References (14–17) for additional information on future applications.

SPECTROSCOPIC METHODS OF ANALYSIS—DIFFUSE REFLECTANCE SPECTROSCOPY

Herbert Michael Heise

Institute of Spectrochemistry and Applied Spectroscopy, Dortmund, Germany

INTRODUCTION

In the field of molecular spectroscopy, absorption measurements with electromagnetic radiation covering the wavelengths between 200 nm and 20 μ m can be used for analytical applications. By convention, tags such as ultraviolet (UV), visible (VIS), and infrared (IR) were given to special intervals of the spectrum, each yielding different specific information on organic and inorganic substances. The energy for electronic transitions between outer molecular orbitals corresponds to radiation of the first two spectral regions noted, whereas vibrational spectroscopy is connected to the infrared. Here, it can be further distinguished between near- and mid-infrared spectral subregions, which are important for routine analytical work.

In the classic spectroscopy experiment, transmission measurements are performed to analyze the radiation absorption of samples. Today, an additional powerful measurement technique is diffuse reflectance spectroscopy, which can be applied advantageously to scattering samples such as powders and other dispersed systems. It often requires less sample preparation than for a spectrum recorded in transmission. After sample penetration, the radiation is diffusely scattered and partially absorbed before part emerges back at the surface, from where it is detected using various optics and detectors. Beside identification of compounds, quantitative assays for active ingredients and fillers and in general formulation testing are available that often require special chemometric tools. Trace analysis and the study of adsorbed chemicals are additional fields. The combination with separation techniques, e.g., thin-layer chromatography, has been established, where diffuse reflectance measurement techniques are involved.

INSTRUMENTAL ASPECTS OF THE MEASUREMENT TECHNIQUE

Molecular spectroscopy plays an important role in the characterization of pharmaceutical substances (1). For

chemical quality and process control, near-infrared spectroscopy has received much attention in the last years. The pharmaceutical industry was forced to develop fast measurement equipment and techniques for the identification of raw materials on receipt as well as to verify composition of pharmaceutical formulations before the products leave the premises. Some techniques are suited for process analysis because of their speed and lack of sample preparation. Further applications are concerned with the analysis in the laboratory during synthesis of compounds, identification of constituents of competitive products, and determination of additives and coatings. Additional cases can be discussed for which low detection limits are required. For best performance and high precision, instrumentation and sample preparation must be adapted to meet such demanding applications.

Instruments and Accessories

The spectral ranges noted above usually cannot be covered by a single instrument. Spectrometers with a grating monochromator are versatile instruments for recording UV/VIS and near-infrared spectra, which are equipped, depending on the spectral range to be measured, on different detectors [commonly used are silicon detectors: 200–1100 nm, indium gallium arsenide (InGaAs): 800–1700 nm (extended wavelength options are available), and lead sulfide: 1100–2500 nm]. Beside scanning instruments, also diode array spectrometers exist to measure the whole spectrum simultaneously. Other measurement technology uses a set of optical filters; such instruments are widespread in assays of food and agricultural products. A special technology that has been implemented in fast near-infrared spectrometers are acousto-optical tunable filters. Radiation sources such as tungsten halogen lamps, which provide a broad emission spectrum of electromagnetic radiation, may be replaced by light-emitting diodes or tunable lasers, broadening the applicability of future spectrometer systems.

The infrared spectral range is usually served by Fourier transform spectrometers, which contain an interferometer for wavelength dispersion. Today, the spectra are

immediately calculated by using Fourier transformation of the measured interferograms. Such instrumentation can provide better spectral quality in shorter time than monochromator based systems. For the mid-infrared, thermal detectors such as those from deuterated triglycine sulfate (DTGS) or, for fast and sensitive measurements, liquid nitrogen cooled photodetectors such as those from mercury cadmium telluride (MCT) are used, whereas for the near-infrared InGaAs, germanium or indium antimonide (InSb) photodetectors are used. An overview on recent instrumentation is given by Coates (2). It is usual practice to display the infrared spectra with wavenumbers as abscissa (the transformation from wavelength λ , for example in micrometers, to wavenumbers $\tilde{\nu}$, in cm^{-1} , is given by $\tilde{\nu} = 10,000/\lambda$).

Various accessories were designed for recording diffuse reflectance spectra. Apart from special devices developed by different groups and described in the literature, several commercially available types must be noted. A few accessories are shown schematically in Fig. 1, which are representative of the diversity of optics. For a long time, integrating spheres have been in use, in particular for UV/VIS and near-infrared spectroscopy, although a few applications with sensitive MCT detectors also can be found within the mid-infrared (3). Usually, a baffle is placed within the sphere to prevent “first strike” radiation from immediately hitting the detector, which measures the scatter over all angles [hemispherical collection; see Fig. 1(a)].

As an alternative, reflection optics based on ellipsoidal mirrors or segments of such type became widespread. Several commercially available types can be noted, one is typified by Spectra-Tech’s Collector [Fig. 1(b)]. To reduce the specular reflection, a blocker can be applied, which is placed vertically on the sample surface, perpendicular to the optical axis. Another accessory is Harrick’s so-called praying mantis (the name was coined after its appearance), which uses an out-of-plane optical geometry to avoid the Fresnel reflection from the sample surface. The device shown in Fig. 1(c) was designed by us to improve the collection of diffusely back-reflected photons, observing the figures of merit for the case that irradiation and detection optics were to be optimized for optical throughput. Another positive feature of such a design is that small spots on large samples can be studied; for applications, see Heise (4). A critical evaluation of different types of diffuse reflectance accessories, especially for discrimination of specular and diffusely reflected radiation, has been given by Yang et al. (5). For a critical test using a high-absorbing inorganic sample—within an inert low-absorbing matrix of KCl powder, it was found that the specular component within the measured

spectrum was primarily sample rather than accessory-dependent.

Additional accessories are constructed from optical fibers. One affordable material suited for the UV/VIS and near-infrared is quartz, whereby a special quality of low-OH grade quartz provides better transmission, especially at longer wavelengths. Compared with mirror-based systems, the acceptance cone for radiation-gathering is reduced owing to the core/cladding configuration of the fiber light-guides [see Fig. 1(d)]. Bifurcated fiber bundles are often used as accessories, whereby the radiation-delivering fibers are mixed at random with the second fiber bundle, by which the reflected radiation is guided to the detector. The flexibility of such fiber optic probes is enormous and also allows measurements from powdered samples, for example, in opened casks.

The diffuse reflectance of a sample is usually measured against a nearly 100%-reflecting material, analogously to a transmittance measurement [a splendid coverage of standards for reflectance measurements is provided by Springsteen (6)]. Traditionally, freshly prepared MgO or BaSO₄ was used for coating the inner surface of an integrating sphere. For the spectral range of 200–2500 nm SpectralonTM (Labsphere, North Sutton, NH) is now the preferred material because it is inert and easy to handle and process. It is a white thermoplastic resin that exhibits a reflectance larger than 0.99 over the spectral range of 400–1500 nm and larger than 0.95 for wavelengths up to 2500 nm. For the mid-infrared, powdered potassium bromide is usually available or gold-coated sandpaper of different grades, which we preferred. A commercially available standard material, obtainable from the same company as above, is InfraGold, which is a multilayer metallic on a mechanically roughened substrate. It exhibits a reflectance between 0.94 and 0.96 through the spectral ranges, with wavelengths between 1 and 25 μm . For dilution of samples, additional materials others than alkali halides have been proposed, which is presented below.

THEORETICAL CONSIDERATIONS

For spectroscopic studies, different measurement techniques are available. Radiation interacting with the sample may be absorbed, transmitted, or reflected. Usually, Lambert–Beer’s law can be applied for absorbing samples showing no scattering. Reflection at a sample surface can be specular, in particular for a plane geometry as obtained for polished surfaces (also called Fresnel reflection), or diffuse, especially for rough surfaces as found in powders.

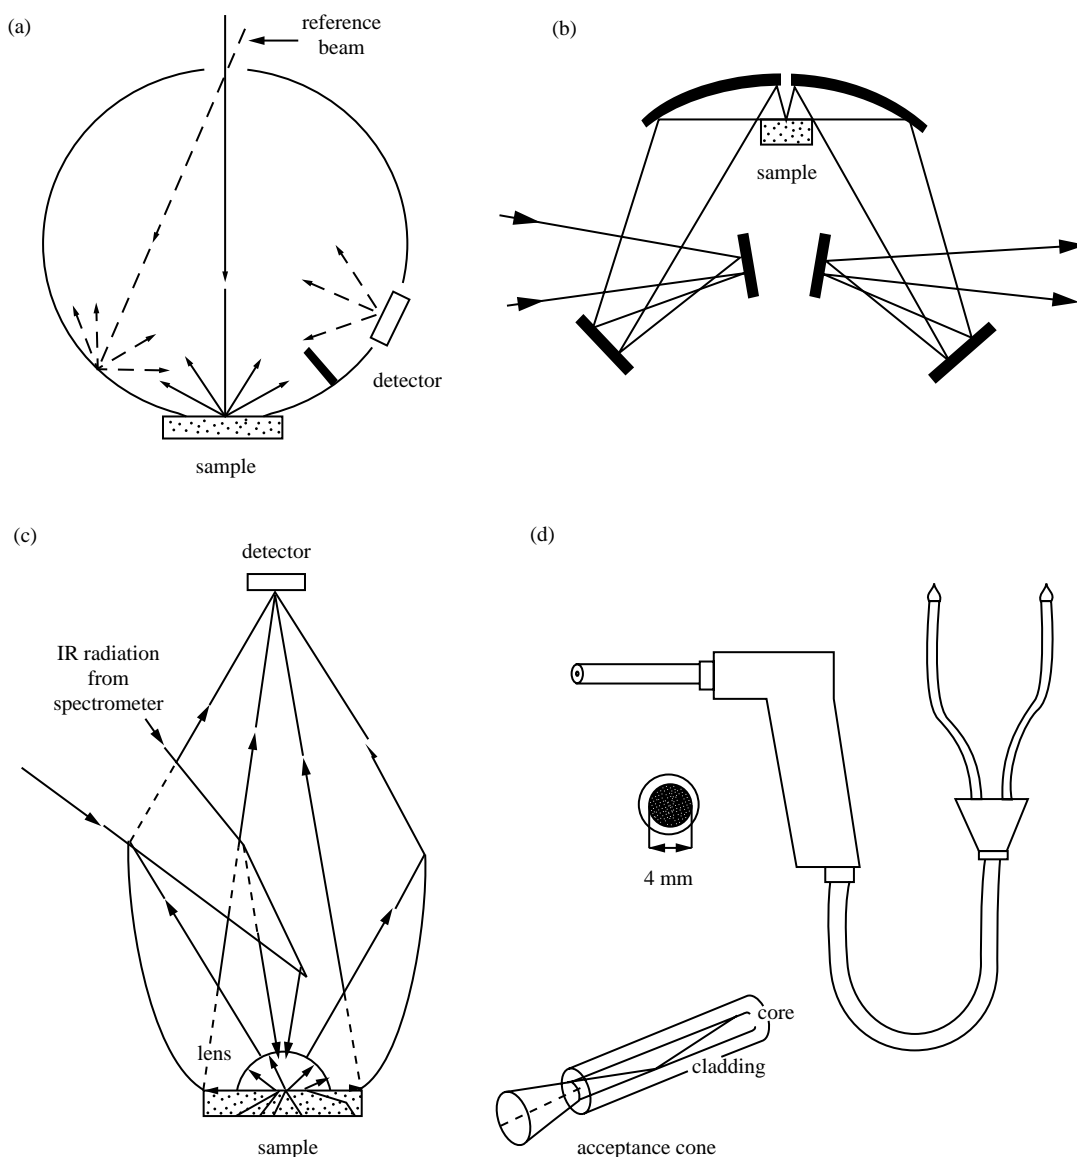

Fig. 1 Accessories for diffuse reflectance spectroscopy: (a) Integrating sphere with hemispherical radiation collection; (b) Accessory based on ellipsoidal mirrors, used within the sample compartment of the spectrometer; (c) Rotational ellipsoidal mirror device with dedicated detector; (d) Bifurcated fiber optic-based accessory (also shown is the random mixture of fibers for illumination and detection; compared with devices based on reflection optics the acceptance cone for radiation delivery and collection is limited and depends on the refractive indices of the core and cladding material).

Many reflections are a combination of both diffuse and specular components. Whereas specular reflectance can be rigorously treated using the Fresnel equations, more complex processes are responsible for the diffuse reflection inside a scattering system. With dispersed systems, further phenomena of interaction between radiation and materials must be addressed. When radiation penetrates into a dispersed sample, the impinging radiation is partly absorbed and partly scattered by the particles so that

radiation is also reflected in a diffuse manner. This diffusely reflected radiation is useful for analytical applications and, with special functions for linearization of the diffuse reflectance signal, quantitative relations between transformed signal and concentration can be found.

As several researchers have shown empirically, the use of $-\log(\text{reflectance})$ can provide, analogous to a transmittance measurement, a linear relationship between

the transformed reflectance and concentration, if the matrix is not strongly absorbing as can be found for many samples studied by near-infrared spectroscopy (7). This issue is presented in detail below. A different approach based on a physical model was considered for UV/VIS measurements and later also applied within the mid-infrared. A theory was derived by Kubelka and Munk (8) for a simple, one-dimensional, two-flux model, although it must be noted that Arthur Schuster (1905) had already come up with a reflectance function for isotropic scattering. A detailed description of theoretical and practical aspects was given by Kortüm (9). The optical absorption and scattering characteristics are described by its absorption and scattering coefficients k and s , respectively. For diffuse reflectance spectra, the transformation of the reflectance by the so-called Kubelka–Munk (K–M) function can provide a linear relationship for absorption band intensities versus concentrations (the units are often referred to as K–M units):

$$F(R) = (1 - R_\infty)^2(2R_\infty) = k/s$$

R_∞ is the reflectance of an infinitely thick sample (in the near-infrared, this means an approximate 5-mm thickness and more). The theory was recently revisited by Loyalka and Riggs (10), who reinvestigated the accuracy of the Kubelka–Munk equations. They found that the coefficient k must be replaced by $k = 2a$ with the absorption coefficient $a = \ln(10) \varepsilon c$, as derivable from Beer's law; for the latter equation: $\ln(10) = 2.303$, ε the molar absorptivity, and c the molar concentration. Such a dependency for k was stated earlier by other researchers when comparing more refined radiation transport theories for biomedical applications, e.g., Ref. (11).

It must be kept in mind that the K–M theory does little more than provide an empirical model useful for quantitative work. To derive at the above equation, several assumptions were necessary such as infinite lateral extension and optical thickness, isotropy of the sample, and diffuse illumination, of which in particular the last is not met in practice when a directional sample illumination is prevailing. For isotropically scattering samples, a so-called three-flux approximation to the near-infrared radiative transfer within pharmaceutical powders and mixtures was presented recently for the derivation of scattering and absorption coefficients (12). Earlier, Hecht had studied different approaches and compared modeling results with measurements primarily in the visible (13). When the scattering inside the medium shows anisotropy as, for example, with forward scattering, more sophisticated modeling of the radiation transport inside the scattering medium is required. One tool applied recently

for spectrum prediction is Monte Carlo simulations, by which statistical averages are obtained for a large population of photons using probability functions for the scattering events. In particular, such an approach is often used for biomedical studies to analyze the photon distribution in tissues after irradiation.

Most spectroscopic software can convert spectra to K–M units on demand. With a constant scattering coefficient, at least within a limited spectral range, the transformed spectra resemble those obtained by conventional transmission spectroscopy. The relative error for K–M unit-based intensities is minimal for reflectance values between 0.2 and 0.7, which is a similar statement as obtainable for absorbance values derived from transmittance measurements and their error estimate. Studies with concern of a varying change in the reflectance of the reference material and its influence on the sample K–M units were carried out by Krivácsy and Hlavay (14).

PRACTICAL ASPECTS

The measurement of diffuse reflectance spectra from powdered samples requires less sample preparation than for the recording of transmittance spectra from solids, for which the embedding of such samples in a transparent medium is usually carried out. For mid-infrared measurements the KBr pellet technique is routinely used in the laboratory, which requires the application of high pressures to get a transparent tablet. The limitations are that the inertness of this embedding material is sometimes not given with the result of unwanted reactions. Scattering within the pellet can still exist, which is evident from evolving baseline shifts. The absorptivities of vibrational combination and overtone bands in the near-infrared are weaker than those of related bands in the mid-infrared, where many intensive bands can be assigned to fundamental vibrations. This leads to the consequence that the amount of substances required for achieving significant absorbances is much larger than for KBr pellet measurements in the mid-infrared.

In Fig. 2, a comparison of two spectra of anhydrous glucose is shown. The upper trace was recorded in transmission. For this, the pellet was placed in front of the spectrometer's detector to reduce the attenuation effects by scattering from inhomogeneities inside the pellet, because placing the pellet into the conventional sample compartment did not allow a satisfactory spectral signal-to-noise ratio. The lower spectrum was obtained using the diffuse reflectance technique on the powder, which was placed in a cup and slightly compressed by a spatulum,

Fig. 2 Comparison of near-infrared spectra of crystalline anhydrous glucose. Spectrum measured in transmittance using the KBr pellet technique [spectral resolution 64 cm^{-1} ; intensity data in absorbance (top trace) and diffuse reflectance spectrum using a spectral resolution of 32 cm^{-1} and intensity data transformed to $-\log(R)$ (bottom trace)].

illustrating the ease of sample preparation. Slight differences in the spectroscopic features arise only from the reduced spectral resolution, as used for the transmittance spectrum shown here.

The high-information density of mid-infrared spectra is well-known. In comparison, the discrimination power of near-infrared spectroscopy is illustrated in Fig. 3(a) for different monosaccharides, for which diffuse reflectance spectra were recorded. Fig. 3(b) shows the near-IR spectra of two pharmaceutical substances. In Fig. 4, the influence of finer particles, obtained by grinding the crystal material from the supplier pack on the spectrum is presented. With coarser particles, the band absorbance intensities are enlarged owing to a decrease in scattering, which means that radiation can penetrate deeper into the sample. In addition, a nearly constant attenuation can be observed, which leads just to a positive offset in the $-\log(R)$ spectrum. However, there are more severe distortions in a K–M transformed spectrum owing to baseline shifts, as pointed out by Griffiths (7).

The spectra of undiluted substances are influenced by effects from Fresnel reflection owing to strong absorption bands found within the mid-infrared spectral range. Additionally, the contrast between band intensities of strong and weak absorption bands is dramatically reduced. An example is provided in Fig. 5, which compares a KBr pellet spectrum of caffeine with that obtained from a powdered undiluted sample by using the diffuse reflectance technique. Two different representations were chosen, one with a transformation into K–M units and a

Fig. 3 Diffuse reflectance near-infrared spectra of several pharmaceutical compounds: (a) Comparison of the spectra of three different monosaccharides measured as crystalline powders; (for clarity, the spectra of fructose and galactose are offset; spectral resolution 32 cm^{-1}); (b) Comparison of spectra of pure caffeine and paracetamol (offset, spectral resolution 32 cm^{-1}).

second with $-\log(R)$. The latter shows uniquely that by using the reflectance technique, a tremendous amplification of weak absorption bands can be achieved. The distribution of intensity ratios is closer to that of the transmittance spectrum, when a dilution of the caffeine by KBr powder, for example, by a factor of 100, is used. A close-up of the mid-infrared fingerprint region in Fig. 6 provides us with the clues as to why a dilution by embedding the compound into the KBr powder must be recommended to obtain a spectrum by diffuse reflectance, which is comparable with the KBr pellet absorbance spectrum.

For strong absorption bands, a large Fresnel component shows up within the diffuse reflectance spectrum, leading to severe band distortions, which are also unmodeled by the K–M theory; the undiluted substance spectrum, in this

Fig. 4 Diffuse reflectance spectra of crystalline urea illustrating the effect of particle size (for the top trace, the crystalline material was unprocessed from the supplier's container), whereas for the bottom spectrum, the substance was ground to finer particles.

example of pure caffeine, shows significant shifts and band shape changes that cause certainly difficulties when comparing such a spectrum with those from spectral libraries, built from absorptivity data that were obtained from standard transmission or similar attenuated total reflection measurements. With a high-absorption index κ , which is related to the absorption coefficient by $a = \ln(10) (4\pi/\lambda)\kappa$, with λ the wavelength of the impinging radiation, the Fresnel reflection can reach unity. In this case, the band is also called the Reststrahlen band. There are applications to use the effect, e.g., for narrow optical reflection band pass filters.

Similar cases with high absorptivities can be found in the UV/VIS region, in which fundamental electronic absorptions exist. When particle size increases, the proportion caused by specular reflectance may become stronger and readily evident in the diffuse reflectance spectrum. A discussion of previous UV/VIS work is given by Wendlandt and Hecht (15).

In the past, extensive investigations were made to obtain better insight into the limitations of the diffuse reflectance measurement technique. Studies demonstrated that sample properties such as particle size and packing affect, in addition to the optical constants, the diffuse reflectance spectrum (9, 15). The characteristics of the diffuse and specular components were studied for different particle sizes and dilution within a nonabsorbing inert matrix. It was found that specularly and diffusely reflected radiation coexist in the measured diffuse reflectance spectrum, even in KCl-diluted samples. In addition, the specular component, which is certainly sample-dependent, is not necessarily the same as from the front-surface

Fig. 5 Comparison of mid-infrared spectra of caffeine obtained by diffuse reflectance and transmission spectroscopy. (a) Diffuse reflectance spectrum of the pure powdered substance with transformed intensity data in K-M units. (b) Same diffuse reflectance spectrum, but using $-\log(R)$ transformation (top trace), the lower spectral range was limited by the cut-off of the MCT detector used; the bottom trace shows a transmission spectrum using the conventional KBr pellet technique transformed into absorbance, i.e., $-\log(\text{transmittance})$.

reflection (16). To prove this, a top layer of pure KCl powder was repeatedly put on top the sample to prevent front-surface reflectance. Another study to be noted is by Brimmer et al. (17) who also discussed the effect of Fresnel reflection with accessories of different optical geometries on the diffuse reflectance spectra.

The penetration depth of the probing IR-radiation is determined by both the scattering and the absorbing characteristics of the sample. Theoretical calculations were carried out by Fraser and Griffiths (18), showing that for strong and medium absorptivities, the criterion of an infinitely thick sample layer is valid for 1 mm, whereas for weaker bands, approximately about 5 mm of sample thickness was claimed. For pure KCl, under the conditions of a defined particle size distribution for the powder and the application of a certain pressure to obtain a

Fig. 6 Spectral differences in mid-infrared spectra of caffeine measured under different conditions. Diffuse reflectance spectrum of the pure crystalline powder (top trace), diffuse reflectance spectrum of 1% of caffeine in KBr-powder (middle trace, intensity data for both spectra in K–M units), and absorbance spectrum as recorded using the KBr pellet technique (bottom trace).

reproducible compression of the disperse sample, a depth of 2 mm was found to reach the K–M requirements of an “infinite” sample thickness, i.e., a further increase in depth causes no change in the measured reflectance (14). The packaging density of the sample, as just noted above, is another parameter that affects the spectrum. The effect of pressure applied to powders for reproducible measurements was studied also by several other spectroscopists [see, for example, Ref. (19)].

Many other materials were studied as matrix materials for diffuse reflectance spectroscopy. Beside the previously noted alkali halides, other examples are silver halides, diamond, germanium, silicon, and chalcogenide glass, preferably of small particle diameters. For an extensive survey on different matrices, see Ref. (20).

A study of the precision and accuracy limiting factors of quantitative assays using diffuse reflectance was carried out by Krivácsy and Hlavay (21), comparing these against transmission measurements. Beside a reproducible sample preparation, the effect of using an underestimated reflectance value of the reference standard ($R_{\infty,r} < 1$) in the K–M transformation approach for the quantitative

evaluation of the spectra leads to a negative intercept for the calibration curves and a slightly reduced linear regression coefficient. Another prerequisite is that scattering stays constant, which is achieved by embedding the sample in a non-absorbing matrix, e.g., of KBr powder with a defined particle size distribution.

The linearity of the K–M function has been investigated for several different conditions. For caffeine, as diluted in KCl powder and reaching up to 100% of weight, maxima of weak and strong absorption bands were tested for this important analytical parameter. It was found that under the conditions given, the use of an accessory with off-axis optical geometry and with application of crossed polarizers before and after the sample, reduced contributions from specular Fresnel reflection from particles on the upper sample surface. As a result, the linear region of the absorbance–concentration dependencies was extended (22). For near-infrared spectra, an alternative linearization function for the measured diffuse reflectance based on $-\log(R)$ is noted above. An intensive investigation on the effect of an absorbing matrix was carried out by Olinger and Griffiths (23), who stated that the concentration range over which linearity holds depends on particle size and matrix absorption strength. The effects of nonlinearity are even more pronounced for mid-infrared spectra (24). Such consequences have to be taken into account when analyzing the *in situ* spectra of adsorbates on substrates, such as from thin-layer-chromatography plates. The combination of spectroscopy with separation techniques is presented below in greater detail.

An interesting study for the interpretation of diffuse reflectance spectra of powders and bulk materials was carried out by Chaffin and Griffiths (25) for the extended near-infrared spectral range, reaching from 10,000 to 2500 cm^{-1} as defined by the authors. The effects of absorption saturation and Fresnel reflection for different amounts of sample scattering are presented. Reducing the scattering inside the studied material, e.g., by application of a transparent liquid for matching the matrix refractive index, a tremendous enhancement of the absorption could be demonstrated, as predicted by the K–M theory.

Because a diffuse reflectance spectrum is scatter-dependent, information on mean particle sizes is also obtainable, which is a parameter of great importance in powder technology. An approach using near-infrared spectrometry combined with multivariate calibration has been presented by Ilary et al. (26). Included was a spectrum standardization by multiplicative scatter correction (see later).

A nonconventional approach for the qualitative analysis of difficult solid samples is to use silicon carbide abrasive paper. The sample is rubbed against the rough surface, and

a small amount sticks to the substrate. A diffuse reflectance accessory is used for recording the spectrum, obtained from a "sample loaded" substrate measurement that is ratioed against that of a clean spot. Recently, metal-coated substrates were found to be even better suited, because the signal-to-noise ratio could be improved owing to much higher reflectivity, compared with the results from using uncoated abrasive paper (recommended grit size, 400). For extremely hard materials, a diamond-in-metal sampling device was used successfully (27).

For qualitative and quantitative mid-infrared studies, a dilution of a sample by a scattering, but transparent matrix is highly recommended. The diffuse reflection technique can be used for low concentrations because of enhancement effects for weak absorptions, which do not exist for transmission measurements. On the other hand, the dilution by KBr powder can add spectral impurities, and the grinding process itself carried out in a humid atmosphere could lead to an increase in water absorption band intensities owing to the hygroscopic nature of the KBr powder. Therefore, great care has to be taken when working with such a material, which should be kept dry in a desiccator or dried again in an oven. In Fig. 7 an example of a diffuse reflectance spectrum of a KBr powder is shown, for which the reference measurement was carried

out using a gold-coated diffusely reflecting substrate. As evident from the baseline offset in the spectrum, the reflectance of the KBr powder is lower than that of the gold-coated standard. The intensification of absorption bands from impurities, either inherent to the KBr used or from a polluted atmosphere, is again to be stressed when using the diffuse-reflectance technique. In this context, suprapure KBr batches and a clean bench are prerequisites for improving assay limits (28).

Diffuse reflectance has also been used extensively for trace analysis. In such a case, the sample to be studied is dissolved using a volatile solvent and transferred to KBr powder, preferably in microcups. The solvent is evaporated, and the sample has coated the KBr particles. With microsampling techniques, sample loadings lower than 100 ng can give satisfactory spectra. If strict rules for avoiding impurities and contamination are observed, detection limits even at the low nanogram level can be reached. Examples from the literature are the identification of different pharmaceuticals (28) and of chlorodibenzo-dioxins isomers (29).

When coupling separation techniques such as thin-layer chromatography (TLC) and liquid chromatography (LC) with infrared spectroscopy for component identification and, less successfully, for quantification, the diffuse reflectance technique has often been applied. Lowest detection limits were usually obtained when the analyte was isolated from its matrix, i.e., the TLC substrate or the eluent in the case of LC-IR coupling. The dissolved compound is usually transferred to a transparent powder, from which it is detected after solvent elimination [see, for example, Ref. (28)]. In situ measurements on TLC plates were also carried out by this and other groups (30). However, because of the strong and broad background absorptions from the stationary phase, such as cellulose, Al_2O_3 , silica gel, and others, analyte detection limits deteriorate significantly compared with the case of a transparent matrix. In addition, substrate interactions with the separated component can often be noticed, which may cause drastic spectrum changes and certainly lead to difficulties with library searching if only normal solid-phase spectra are implemented for reference. Liquid chromatography with polar eluents, as used in reversed-phase LC, complicate the solvent elimination step, although interfaces have been constructed to enable an on-line analysis of effluents from reverse-phase high-performance liquid chromatography (RP-HPLC) (31). A review of analyte deposition-based concepts for such separation techniques is given by Somsen et al. (32). The incorporation of HPLC/FT-IR into pharmaceutical research programs and its automation are discussed by Pivonka and Kirkland (33).

Fig. 7 Diffuse reflectance spectrum of KBr powder measured against a gold-coated diffuse reflective substrate transformed to either $-\log(R)$ or K-M units. The spectral reflectance of KBr powder is lower than that of the gold-coated standard. Furthermore, various absorption bands are noticeable: the broad band approximately at 3500 cm^{-1} and that at 1640 cm^{-1} is from adsorbed water. The doublet at 2350 cm^{-1} is from uncompensated atmospheric CO_2 within the spectrometer and accessory; bands between 1500 and 1000 cm^{-1} arise from inorganic impurities, and bands below 3000 cm^{-1} are from compounds containing aliphatic groups.

CHEMOMETRICS

Quality control, pharmaceutical product identity checks, and quantification are important fields in the broad application of the different spectroscopic methods. There are many spectroscopic aspects, e.g., concerning sample preparation, influences from different accessories, and possibly spectrometer effects, which certainly influences quantitative measurements. The latter problems could be solved using calibration transfer between different spectrometer types, for example, a scanning and an FT-near-IR spectrometer (34).

For qualitative spectrum interpretation, the conventional method for routine identification of chemical species is a library-search, based on spectral mapping algorithms. Before library-searching spectral preprocessing, i.e., elimination of baseline effects and noise, standardization, etc., is performed on the sample spectrum. Comparison of such a processed spectrum with a candidate library spectrum can be based on different principles such as correlation of spectra, similarity and distance measures, and logical operations. For an overview see Ref. (35). For the mid-infrared spectral range, many libraries are available, although only a limited number of spectra might have been recorded with the diffuse reflectance technique. On the other hand, industrial activities are on the way for near-IR libraries, in particular, recorded using the diffuse reflectance technique. For the UV/VIS range, only limited digitized information is available, whereas most spectra are from solution work. A more difficult situation is found for mixtures aiming at component identification. For a discussion and applied strategies, see Ref. (36). Procedures for classifying and interpreting spectra can be based on chemometric tools such as factor analysis, pattern recognition, cluster analysis, and artificial intelligence algorithms (37). Spectral deviations can sometimes be traced back to differences in chemical purity (e.g., water content), particle size, and size distribution or polymorphism (38). Recently, pattern recognition methods were applied for near-infrared detection of polymorphic forms and their conversion. The methods were robust enough when applied to different spectrometers to avoid the need for multivariate instrument standardization (39).

Quantification is another important field in which fast results are needed for process analysis and quality control. Multivariate techniques play an important role in quantitative assays, for which different strategies and algorithms are in use for calibration. Individual wavelength and full-spectrum methods are in use: multiple linear regression (MLR) is an example of the first category, whereas partial least-squares (PLS) and principal

component regression (PCR) usually make use of broad spectral interval information. For more details, see Refs. (40, 41). Apart from so-called full-spectrum methods, spectral variable selection is a playground of chemometricians for achieving improved and more robust calibration models. A recent study also provides a review on the activities in this field (42).

It must be mentioned again that quantification based on diffuse reflectance spectra requires a reproducible sample preparation, because the reflectance depends on particle size and shape, packing density, and the texture of the sample surface. Therefore, sample preparation must be controlled (using same grinding time when using a ball and mill grinder and pressurizing the sample reproducibly). A recent example was provided by Blanco et al., who tested multivariate calibrations for active compounds in pharmaceutical mixtures based on partial least-squares regression in combination with different spectral-preprocessing methods (43). Often, baseline effects are eliminated by taking first or second derivatives of the spectral data, and, in particular, multiple scatter correction is an important preprocessing method used for the standardization of diffuse reflectance spectra (44).

PHARMACEUTICAL APPLICATIONS

The number of applications of diffuse reflectance spectroscopy for pharmaceutical analysis has increased tremendously in recent years. An overview to the activities up to 1986 is found in the first edition of the *Encyclopedia of Pharmaceutical Technology* (45). The on-line identification of pharmaceutical raw materials has been noted above because of the requirements of Good Manufacturing Practice (GMP), which is most often performed now using near-infrared spectroscopy. On the other hand, mid-infrared spectroscopy can provide more information owing to the fact that more vibrational bands from all possible molecular substructures show up within this spectral range, whereas the near-infrared comprises primarily bands corresponding to overtones and combination bands, just involving vibrations with C—H, O—H, and N—H molecular bonds. The superiority of mid-infrared spectroscopy compared with measurements in the near-infrared was shown when a special formulation type and the quantification of the active ingredients were required (46). Other applications are concerned with the development of rapid, reliable, and noninvasive testing assays for whole tablets or intact capsules. Lodder et al. described analyzing several kinds of inorganic compounds through a gelatin wall; their aim was the detection of

capsule-tampering using a special clustering algorithm, which was based on near-infrared reflectance analysis (47). Another direct control of the active ingredient included in tablets without extraction or pulverization by near-infrared spectrometry was possible, as shown by other scientists (48).

Near-infrared spectroscopy was proposed as an alternative to several compendial test methods. As an example, ampicillin trihydrate was used to demonstrate that in total, eight quality criteria could be checked and its "conformity index" calculated (38). Additional chemometrics for quality control were developed by the same group (49). Their strategy was used to distinguish differences in mean particle size of various lactose samples and to study the effectiveness of a blending process for homogenous mixture preparation.

Another task often required is the determination of the water content. Quantification of moisture in hard gelatin capsules was described by Berntsson et al. who discussed its importance in monitoring for at-line process control (50). A sparse MLR calibration model with three optimized near-infrared wavelengths yielded an absolute prediction error of 0.1% over a range of 5.6–18% water content. For monitoring the production process, Han and Faulkner (51) analyzed the spectral range of 1100–2500 nm. Second derivative spectra were used for PLS calibration of moisture. Single-wavelength analysis was applied for coating thickness. Furthermore, identification of tablets inside blister packaging was also possible.

A fiber optic probe was used by Blanco et al. (52) for analysis of spasmocetyl samples with the active compound otilonium bromide and cellulose, maize starch, sodium starch glycolate, and glyceryl palmitostearate as excipients. Another study from this group covered the identification, qualification of the substance, and the quantification of the active component. A library search with a comparison to the near-infrared spectra of 163 pharmaceuticals was involved (53). An on-line monitoring for the determination of the endpoint of polymorph conversions in pharmaceutical processes was recently described (54); further investigations into this field were published and are noted previously (39).

An interesting application is the nondestructive identification of pharmaceutical tablets directly through a blister packing using a fiber optic probe (55). Three different pattern recognition methods based on full near-infrared spectra and subset wavelength ranges were tested to discriminate between film-coated and nonfilm-coated tablets as well as between active and placebo tablets. Dreassi et al. (56) used near-infrared FT spectroscopy for the quality control of solid pharmaceutical formulations. Quantitative assays were developed

for solid drug preparations, for pills containing ibuprofen and tablets with paracetamol, and for powders containing benzydamine hydrochloride and tricetol. Additional work for qualitative and quantitative analysis aimed at all stages of the production, including determination of moisture, was also described by Dreassi et al. (57). Another study was concerned with the characterization of several pharmaceuticals on the basis of their physical properties, i.e., crystalline states and densities (58).

In conclusion, it can be stated that spectroscopic techniques will further dominate the analytical tools of the future with respect to qualitative and quantitative assays. This is because of their speed and the enormous information content of the spectra, especially in the infrared, and the fact that reagent-free multicomponent methodologies are available. The widespread diffuse reflection technique certainly has to compete with others in the laboratory and at the production site. However, for the study of bulk and dispersed systems, it will often be the method of choice. There are additional developments concerned with dedicated instruments and user-friendly interfaces, in which chemometrics play an important role. It is hoped that the sophisticated algorithms presented in the literature will be available soon within expert systems, allowing adaptations to special applications and broadening the general acceptance of these spectroscopic methods presented above.

SPECTROSCOPIC METHODS OF ANALYSIS— FLUORESCENCE SPECTROSCOPY

Stephen G. Schulman

Jeffrey A. Hughes

University of Florida, Gainesville, Florida, U.S.A.

INTRODUCTION

Luminescence processes in molecules can be classified according to the source from which the excitation energy is derived. In photoluminescence, which encompasses fluorescence and phosphorescence, excitation is achieved by the absorption of light by the potentially luminescent molecule. In chemiluminescence, excitation occurs as the result of an energetic chemical reaction. Fluorescent analytical methods make up the great majority of the ultrasensitive assays carried out by light emission spectroscopy in the pharmaceutical sciences. Although they are more complicated, there has been some interest in phosphorescence and more in chemiluminescence. Accordingly, these phenomena are also briefly treated here.

MOLECULAR ENERGY LEVELS AND ELECTRONIC PROCESSES

Light absorption by an organic molecule results in the promotion of a single electron to a higher energy molecular orbital. The excited state of the molecule thus formed then has two electrons in singly occupied orbitals. The promoted electron and the one it left behind in the orbital it originally occupied can have spins that are opposite (as in the ground state), or they may have the same spin. If the electrons have opposite spins, the molecule is said to be in an excited singlet state. If, on the other hand, they acquire the same spin, the excited molecule is said to be in a triplet state. For each excited singlet state, there is a triplet state that, owing to lower electrostatic repulsion in the latter, has a somewhat lower energy than the corresponding singlet state. Luminescence originating from the electronic transition of a molecule in passing from an excited singlet state back to the ground state is called fluorescence. That originating from the transition from an excited triplet state to the ground state is called phosphorescence.

Transition may occur from the ground singlet state to a number of excited singlet states and to any of a number of vibrational levels within each of these excited singlet states as a result of scanning the sample of interest with the range of wavelengths (energies) of light that lie in the visible and near-ultraviolet regions of the electromagnetic spectrum. These electronic transitions produce the electronic absorption spectrum of the compound of interest. The “vibrational breadth” of each upper electronic state results in the broad-banded appearance of the absorption spectra of molecules, which is unlike the line-like appearance of the absorption spectra of atoms.

Subsequent to excitation, excess energy is rapidly lost by the excited molecules in collisions with the solvent. Each collisional loss of energy causes vibrational and sometimes even electronic changes in the excited molecule, which are radiationless (i.e., no light is emitted). These changes are called vibrational relaxation in the case of vibrational change and internal conversion in the case of radiationless electronic transition. In unconjugated molecules where there is great vibrational freedom, these processes may carry the excited molecule back to the ground electronic state. However, in highly conjugated molecules, especially aromatic molecules, vibrational motion may be restricted, and vibrational relaxation and internal conversion may carry the excited molecule only back to the lowest vibrational level of the lowest excited singlet state. From this state, which is about 10^6 times longer-lived than the upper vibrational and electronic states, the molecule may return to the ground electronic state by light emission (fluorescence), or it may undergo photochemical reaction or a change in spin of one of its electrons. When the latter process occurs, the molecule is said to undergo intersystem crossing, a process that results in the creation of the lowest triplet state. If light emission occurs in the demotion of the molecule from the triplet state back to the ground singlet state, it is called phosphorescence. Phosphorescence entails a change in angular momentum of the emitting molecule and is classically forbidden. This is manifested in the long decay-time of phosphorescence (10^{-4} –10 s). Fluorescence decay-times

(reciprocal probability of decay) are typically 10^{-11} – 10^{-7} s. Both forms of light emission are analytically useful, but fluorescence occurs under a much wider variety of circumstances and has been used for analytical purposes far more than has phosphorescence.

Because fluorescence and phosphorescence originate exclusively from the lowest vibrational level of the lowest excited singlet and triplet states, respectively, and terminate in any of a number of vibrational levels of the ground electronic state, there will be only one possible fluorescence band and one possible phosphorescence band observable from a single chemical species capable of fluorescing and/or phosphorescing. More than one of either is indicative of extraneous luminescing species, either impurities or products of photochemical reaction.

CHARACTERISTICS OF LUMINESCENCE SPECTRA

Fluorescence

Fluorescence is characterized by two spectra corresponding to excitation and emission. In solutions, both spectra usually appear as broad bands that may or may not show vibrational fine structure. The excitation and the absorption spectra of a compound should be the same, but with ordinary fluorescence spectrophotometers, a distorted version of the true absorption spectrum is obtained. The degree of distortion depends on the light output of the spectral excitation source and the responses of the monochromators and detector as functions of the wavelengths of exciting light. The excitation spectrum can be useful in the qualitative and quantitative analysis of mixtures. For example, the excitation spectrum of one component of a mixture can be isolated by setting the emission monochromator at the proper wavelength, provided the absorbance spectra of compounds present in the mixture differ sufficiently.

The difference in energy between the longest wavelength absorption band and the fluorescence band of an analyte is called a Stokes' shift and is usually no more than 100 nm. If the fluorescence band shows an unusually large Stokes' shift, then either the solute exhibits some form of photochemical behavior such as isomerism or prototropic dissociation in the excited state, or more than one fluorescent species is present.

The shape of the fluorescence spectrum is independent of the wavelength of light used to excite it because the fluorescence always takes place from the same level, no matter to what level the molecule was originally excited.

Quantum yield and decay-time of fluorescence

Because of the other processes that compete with fluorescence for deactivation of molecules in the lowest excited singlet state, only a fraction of the excited molecules will return to the ground state by fluorescence. This fraction is called the quantum yield of fluorescence (Φ_f) or fluorescence efficiency. Under given conditions of temperature and environment, Φ_f is a physical constant of the excited molecular species. Φ_f usually decreases with increasing temperature. The actual mean time the molecule spends in the excited state before fluorescing is referred to as the lifetime of the lowest excited singlet state (or fluorescence decay-time) and is represented by the symbol τ_R^0 . The time it would spend in the lowest excited singlet state if there were no other processes competing with fluorescence is called the natural life time, τ_R . The quantum yield of fluorescence, then, may be expressed as being equal to τ^0/τ_R^0 . Because it is a fraction (never greater than unity), τ_R^0 is always greater than or equal to τ^0 . The intensity of fluorescent light emitted depends on the concentration and molar absorptivity of the absorbing (ground state) species and the quantum yield fluorescence of the fluorescing (excited state) species.

Phosphorescence

Phosphorescence is also characterized by an excitation and an emission spectrum. Because the lowest triplet state invariably lies lower in energy than the lowest excited singlet state of the same molecule, phosphorescence will occur at wavelengths longer than those of fluorescence and, therefore, at wavelengths much longer than those of the excitation spectrum. As in the case of fluorescence, the phosphorescence spectrum and the phosphorescence excitation spectrum are distorted by the instrumental components and therefore do not represent "true" spectra.

Because of the long radiative lifetime of the lowest triplet state, most phosphorescence in fluid solutions is obviated by collisional quenching, especially by dissolved molecular oxygen. Phosphorescence, when it occurs, is usually observed at low temperatures (e.g., that of liquid nitrogen) in rigid matrices where it may demonstrate high quantum yields. In the past three decades, much interest has been focused on phosphorescence at room temperature (RTP), which sometimes can be observed in samples adsorbed on solid substrates such as filter paper. Unfortunately, the quantum yields observed in room temperature phosphorescence are low, leading to poor analytical sensitivity, and the method has not enjoyed wide popularity. Phosphorescent measurements at low temperatures require special handling techniques and are difficult to

reproduce. Consequently, although low-temperature phosphorimetry is inherently a very sensitive analytical method, it too has yet to attract a substantial group of users. However, there are a substantial number of molecules of pharmaceutical interest that phosphoresce but do not fluoresce (e.g., metronidazole) or fluoresce weakly and phosphoresce intensely (e.g., warfarin), and it is probably worthwhile to pursue phosphorimetry as a valuable aspect of molecular luminescence spectroscopy.

Chemical Structural Aspects of Fluorescence Spectra

Fluorescence spectra of analytical and pharmaceutical interest arise from functionally substituted aromatic molecules, particularly those derived from benzene, naphthalene, and anthracene or their heteroaromatic analogs pyridine, quinoline, isoquinoline, and acridine.

The intensity of fluorescence observable from a given molecular species depends primarily on the quantum yield of fluorescence, which may affect the intensity of fluorescence over about four orders of magnitude and may determine whether fluorescence is observable at all. The quantum yield of fluorescence is dependent on the rates of processes competing with fluorescence for the deactivation of the lowest excited singlet state. These, in turn, depend on molecular structure.

Aromatic molecules, containing lengthy aliphatic side chains, generally tend to fluoresce less intensely than those without the side chains. This is brought about by the introduction of a large number of vibrational degrees of freedom by the aliphatic moieties, providing an efficient pathway for internal conversion. In the unsubstituted aromatic molecules, the rigidity of the aromatic ring results in wide separation of the ground and lowest excited singlet states. In general, molecular rigidity and high quantum yield of fluorescence are closely related.

The fluorescence efficiencies of aromatic molecules are reduced by heavy atom substituents such as bromine and iodine and by certain other groups such as aldehyde and keto as well as nitro groups. However, in many cases the substituents that decrease the intensity of fluorescence enhance the intensity of phosphorescence. Consequently, aromatic nitro compounds, bromo- and iodo-derivatives, aldehydes, ketones, and some *N*-heterocyclics tend to fluoresce very weakly or not at all. However, most of them phosphoresce quite intensely. On the other hand, many substituents that are electron donors such as amino, hydroxy, and methoxy often tend to increase the quantum yields of fluorescence of molecules to which they are attached.

The energies of the ground and lowest excited singlet states of fluorescing molecules are affected by such features of molecular structure as the presence of substituents and the molecular geometry. This is reflected in the position (energy) of the fluorescence band maximum in the spectrum. The greater the separation between the ground and lowest excited singlet states, the greater will be the frequency and the shorter will be the wavelength of fluorescence. This separation depends on the energy difference between the highest occupied and lowest unoccupied molecular orbitals and the repulsion energy between the electronic configurations corresponding to the ground and lowest excited singlet states. For aromatic molecules, the greater the extension of the conjugated system, the smaller the energy separation between the highest occupied (π) and lowest unoccupied (π^*) orbitals. Thus, the wavelengths of fluorescence (λ_f) increase with increasing extension of conjugation in the series benzene ($\lambda_f = 262$ nm), naphthalene ($\lambda_f = 314$ nm), and anthracene ($\lambda_f = 379$ nm).

The fluorescence maxima of aromatic compounds with substituents differ from those of the parent hydrocarbons. Groups such as $-\text{NH}_2$, $-\text{OH}$, and $-\text{SH}$ have unshared electron pairs of energy higher than that of the π -electrons of aromatic molecules. These can be transferred into vacant π -orbitals belonging to the aromatic ring. Thus, the energy gap between the highest occupied and lowest unoccupied orbitals of the substituted molecule is considerably smaller than that between the highest occupied and lowest unoccupied orbitals of the unsubstituted (parent) molecule, and the wavelengths of fluorescence in the former are somewhat longer. For example, 1-naphthylamine fluoresces at 372 nm in hexane whereas naphthalene fluoresces at 314 nm in the same solvent.

Groups such as carboxyl and nitrile, which are electron-withdrawing, have localized, vacant, low-energy π -orbitals in the ground state of the substituted molecule. This type of substituent introduces a vacant orbital between the highest occupied and lowest unoccupied π -orbitals of the unsubstituted molecule. The energy gap between the highest occupied and lowest unoccupied orbitals of the substituted molecule is therefore smaller than the gap between the highest occupied and lowest unoccupied orbitals of the unsubstituted molecule. Fluorescence thus appears at longer wavelengths in the substituted molecule than in the unsubstituted molecule. For example, the fluorescence of 2-naphthoic acid lies at 344 nm in hexane, 30 nm longer in wavelength than the fluorescence of naphthalene.

When an electron-withdrawing group and an electron-donating group are attached to the same aromatic ring,

fluorescence may be viewed as involving transition between the lone-pair orbital of the donor group and the vacant π -orbital of the acceptor group. In this case, the energy of the transition is lower and, thus, the fluorescence wavelength is longer than when either group alone is attached to the ring. When two donor groups or two acceptor groups are attached to the aromatic ring, the position of the fluorescence band is usually determined by the donor group with the highest energy lone pair or the acceptor group with the lowest energy vacant orbital.

Solvent Effects

The solvents in which fluorescence spectra are observed play a major role in determining the spectral positions and intensities with which fluorescence bands occur. In some cases, the solvent may determine whether fluorescence is to be observed at all.

Solvent interactions with solute molecules are predominately electrostatic in nature and may be classified as dipolar or hydrogen-bonding. The position of the fluorescence band maximum in one solvent, relative to that in another, depends on the relative separations between ground and excited state in either solvent and, therefore, the relative strengths of ground- and excited-state solvent stabilization.

If the excited state of a polar molecule has a higher dipole moment than its ground state (most molecules are in this class), the excited state will be more stabilized by interaction with a polar solvent than will the ground state. As a result, upon going from a less polar to a more polar solvent, the fluorescence spectrum will shift to longer wavelengths. In a few cases, the ground state of a solute is more polar than the excited state. In this case, going to a more polar solvent stabilizes the ground state more than the excited state, causing a shift to shorter wavelengths with increasing solvent polarity.

Hydrogen-bonding solvents having positively polarized hydrogen atoms are said to be protic solvents. They interact with the nonbonded and lone electron pairs of solute molecules. Hydrogen-bonding solvents having atoms with lone or nonbonded electron pairs are called hydrogen-bond acceptor solvents. They interact with positively polarized hydrogen atoms on electronegative atoms belonging to the solute molecules (e.g., in $-\text{COOH}$, $-\text{NH}_2$, $-\text{OH}$, $-\text{SH}$). Because most hydrogen-bonding solvents are also polar, hydrogen-bonding and nonspecific dipolar interaction are usually both present as modes of solvation of functional molecules. Accordingly, the spectral shifts actually observed on going from one solvent to another are a composite of dipolar and hydrogen bonding effects that may be constructively or destructively additive.

Protic solvents interacting with functional groups that are electron-withdrawing in the excited state (e.g., carbonyl) enhance charge transfer by introducing a partial positive charge into the electron acceptor group. This stabilizes the excited state relative to the ground state so that the fluorescence spectra shift to longer wavelengths, and often the quantum yield of fluorescence increases with increasing hydrogen-bond donor capacity of the solvent. Increasing protic nature of the solvent produces shifts to shorter wavelengths and usually lower fluorescence efficiencies when interacting with lone pairs on functional groups, which are electron donors in the excited state (e.g., $-\text{OH}$, $-\text{NH}_2$). Hydrogen-bond acceptor solvents produce shifts to longer wavelengths and higher fluorescence efficiencies by solvating hydrogen atoms on functional groups that are electron donors in the excited state (e.g., $-\text{OH}$, $-\text{NH}_2$). This is a result of partial withdrawal of the positively charged proton from the functional group that facilitates transfer of electronic charge away from the functional group. Finally, solvation of hydrogen atoms on functional groups that are charge transfer acceptors in the excited state (e.g., carboxyl) inhibits charge transfer by leaving a residual negative charge on the functional group. This results in shifting of the fluorescence spectrum to higher frequency and gives rise to lower quantum yields of fluorescence.

The same considerations are applicable to the influence of the solvent on the phosphorescence wavelength, but the shifts are much smaller than in the case of fluorescence.

pH Effects

The effects of solution acidity and basicity on luminescence spectra result from the dissociation of acidic functional groups or protonation of basic functional groups associated with the aromatic portions of fluorescing and phosphorescing molecules. Protonation or dissociation can alter the natures and rates of nonradiative processes competing with luminescence and, thereby, affect the quantum yields of emission. For example, the antimalarial mefloquine fluoresces very weakly but phosphoresces well in neutral aqueous media. However, at $\text{pH} < 1$, its protonated form fluoresces intensely, and its phosphorescence is very weak.

Protonation and dissociation alter the relative separations of the ground and excited states of the reacting molecules and thereby cause shifting of the luminescence spectra. The shifts tend to be greater in fluorescence spectra than in phosphorescence spectra and are attributable to the electrostatic stabilization or destabilization of the excited state, relative to the ground state, produced by protonation and dissociation. The protonation

of electron-withdrawing groups such as carboxyl, carbonyl, and pyridinic nitrogen causes shifts of the luminescence spectra to longer wavelengths, whereas the protonation of electron-donating groups such as the amino group produces spectral shifts to shorter wavelengths. The protolytic dissociation of electron-donating groups such as hydroxyl or sulfhydryl produces spectral shifts to longer wavelengths, whereas the dissociation of electron-withdrawing groups such as carboxyl produces shifting of the photoluminescence spectra to shorter wavelengths.

One of the interesting aspects of acid-base reactions of fluorescent molecules in fluid solutions is derived from the occurrence of protonation and dissociation during the lifetime of the excited state. This phenomenon affects the dependence of fluorescence on pH and must be considered in the development of a fluorometric analysis in aqueous solutions.

The lifetimes of molecules in the lowest excited singlet state are typically of the order of 10^{-11} – 10^{-7} s. Typical rates of prototropic reactions are 10^{11} dm³ mol⁻¹ s⁻¹ or lower. Consequently, excited-state proton-transfer reactions may be competitive with radiative deactivation of the excited molecules.

In the event that excited-state proton transfer and radiative deactivation are temporally competitive, the quantum yield of fluorescence will demonstrate a complex dependence on the pH level of the solution. Because the electronic distribution of a molecule is usually much different in an excited state than in the ground electronic state, the variation in fluorescence intensity caused by the pH dependence of the quantum yield of fluorescence will occur in a pH region different from the pH region in which the fluorescence intensity depends on the absorbance of the analyte. This means that in an arylammonium ion, for example, which becomes more acidic in the lowest excited singlet state, one might observe fluorescence from the conjugate base at a pH level of zero, even though the pK_a level might be as high as 5.

Quenching

The emission of light by photoexcited luminescent molecules may be decreased or even eliminated by interactions with other chemical species. This phenomenon is called quenching of luminescence.

Two kinds of quenching are distinguished. In static quenching, complexation between the potentially luminescent molecule and the quencher takes place in the ground state. The complex, when excited, fails to luminesce. The efficiency of quenching is governed by the formation constant of the complex as well as by the

concentration of the quencher. The quenching of the fluorescence of doxorubicin by Fe(III) is an example.

In dynamic quenching, the quenching species and the potentially luminescent molecule react subsequent to photoexcitation of the latter and during the lifetime of its excited state. Dynamic quenching is also called diffusional quenching, and its efficiency depends on the viscosity of the solution, the lifetime of the excited state (τ°) of the luminescent species, and the concentration of the quencher (Q). This is summarized in the Stern–Volmer equation (Eq. 1):

$$\Phi/\Phi_f^\circ = \frac{1}{1 + K_Q\tau^\circ[Q]} \quad (1)$$

where k_Q is the rate constant for encounters between quencher and potentially luminescing species, and Φ_f° and Φ_f are the quantum yields of luminescence in the absence and presence of concentration of the quencher (Q), respectively.

Dynamic quenching is also characterized by the dependence of the actual lifetime of the excited state on (Q). In static quenching, the lifetime of the excited state is invariant with respect to (Q).

Concentration Effects

As the concentration of a potentially luminescent solute is increased, the frequency of encounters between solute molecules is increased. This often results in the formation of solute complexes at the expense of monomeric solute molecules. Obviously, such interactions will affect the fluorescence expected from a given solution based strictly on the formal concentration of monomers and can seriously affect the results of a fluorimetric analysis.

In solutions of moderate concentration, there are two types of excited state solute–solute interaction, which are common. An excited polymer, or excimer, may form through the aggregation of excited solute molecules with ground-state molecules of the same type. Fluorescence quenching and/or a spectral red shift may result. Also, a heteropolymeric excited-state complex may form between two different solute molecules. Such a complex is referred to as an exciplex.

The transfer of electronic excitation energy from one molecule to another is another phenomenon that is related to the concentration of potentially luminescent molecules. Energy transfer occurs quite frequently in nature, either by direct collision or even over distances as great as 50 Å or more by a radiationless mechanism by which the excitation energy is transmitted from the molecules that are originally excited (donors) to the recipient molecules

(acceptors). The efficiency with which an excited donor will transfer its excitation energy to an acceptor molecule (rather than fluoresce) is a function of the lifetime of the excited state of the donor, the orientations of the donor and acceptor molecules with respect to one another, and the inverse sixth power of the distance between the donor and acceptor. The energy-transfer process quenches the fluorescence of the donor and often sensitizes the fluorescence of the acceptor.

Temperature Effects

At low temperature, the efficiency of luminescence is usually increased, and the spectra often become sharper. Both effects result from the increase in solution viscosity and thus a decrease in collisional deactivation. In addition to changes in intensity, wavelength shifts also occur when the temperature of a medium is changed. At very low temperature, fluorescence originates from an excited state that is locked into the ground-state equilibrium geometry and solvent cage. At room temperature, in fluid solutions, fluorescence occurs only after the molecular geometry and solvent cage of the fluoresce have adapted to the new electronic distribution characteristic of the excited state. The emitting excited state under fluid conditions is lower in energy than under rigid conditions and, therefore, the fluorescence under the latter circumstance will be at higher energy (shorter wavelength) than in the former.

QUANTITATIVE ANALYSIS

Luminescence spectroscopy is used more often in quantitative analysis than in any other application. The quantitative relationship between fluorescence intensity F and analyte concentration C is derived from the Beer–Lambert law:

$$I = I_0 10^{-\epsilon Cl} \quad (2)$$

where I and I_0 are the intensities of exciting light transmitted through and incident on the sample, l is the length of the light path through the sample, and ϵ is the molar absorptivity of the molecular species of interest at the nominal wavelength of excitation. The intensity of light absorbed I_a is then:

$$I_a = I_0 - I = I_0 (1 - 10^{-\epsilon Cl}) \quad (3)$$

If all molecules absorbing light fluoresced, then I_a would be the intensity of fluorescence. However, only the

fraction Φ_f fluoresces. The remaining fraction $1 - \Phi_f$ returns to the ground state by nonradiative means. Thus:

$$F = \phi_f I_a = \phi_f I_0 (1 - 10^{-\epsilon Cl}) \quad (4)$$

If the absorbance (ϵCl) of the sample is less than 0.02, then to within an approximately 2% error, Eq. 4 becomes:

$$F = 2.3 \phi_f I_0 \epsilon Cl \quad (5)$$

in which F is linear with respect to C . It then remains only to prepare a standard solution of concentration C_s and having fluorescence intensity F_s to be compared with the unknown solution of concentration C_u and fluorescence intensity F_u according to:

$$C_u = \frac{F_u}{F_s} C_s \quad (6)$$

It should be noted that the conditions for Eq. 5 to obtain can be met by either working with very dilute solutions or by exciting in a region of the absorption spectrum where ϵ is small.

Of course, it is always prudent to prepare a calibration curve for several standard solutions to check the linearity of the F versus C plot before attempting the simple relative fluorimetry expressed in Eq. 6 for a large number of samples.

In the case of phosphorescence, the intensity P is related to the concentration of analyte, following similar lines of reasoning applied to fluorescence, according to:

$$P = \phi_{ST} \phi_P I_0 (1 - 10^{-\epsilon Cl}) \quad (7)$$

where Φ_{ST} and Φ_P are the quantum yields of intersystem crossing (the fraction of excited molecules converted from the lowest excited singlet state to the lowest triplet state) and phosphorescence (the fraction of molecules arriving in the lowest triplet state that are deactivated by phosphorescence), respectively. As is the case for fluorescence, Eq. 7 can be expanded and for weakly absorbing solutions can be made analogous to Eq. 6, according to:

$$C_u = \frac{P_u C_s}{P_s} \quad (8)$$

where P_u and P_s are the phosphorescence intensities of the unknown and standard samples, respectively. Eq. 8 is, therefore, the basis of simple quantitative phosphorimetry.

INSTRUMENTATION

The basic components of luminescence instrumentation are generally arranged as shown in Fig. 1. The sample is placed in a sample cell and excited by either ultraviolet or

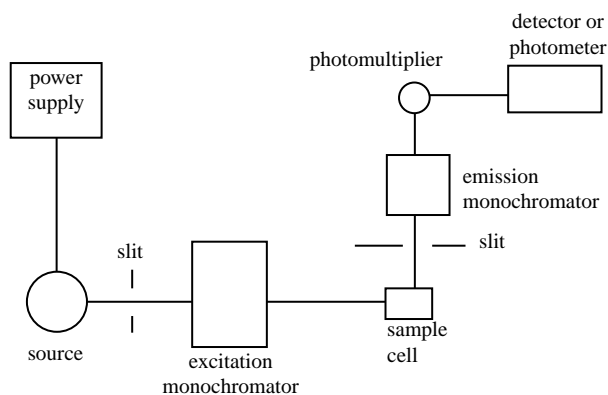

Fig. 1 General layout of luminescence instrumentation.

visible light from a source. A filter or monochromator may select a particular excitation wavelength region. The sample emits luminescence radiation in all directions, but only a portion is observed by the detection system that is usually set at 90° from the source of excitation to minimize the possibility of detecting stray light from the source. Another filter or monochromator may select the emission wavelength region, and a detector would convert the luminescence radiant flux into an electrical signal. An amplifier-readout system amplifies and processes the signal and displays it in the required form.

Sources

Sources of radiant energy are generally classified according to the spectral distribution of the radiation emitted. Continuum sources have a broad spectral distribution covering a large wavelength range. Line sources have spectra consisting of a number of sharp lines or bands. Lasers have allowed the use of extremely narrow bandwidths.

Continuum sources

Incandescent lamps are the simplest type of light source. They usually consist of a heated rod or filament of tungsten in an inert gas such as nitrogen or argon at a pressure of approximately 1 atm.

Radiation emitted by the lamp is caused by the temperature achieved by its filament, which in turn depends on the power input on the lamp. The radiation spectral distribution is a function of the temperature of the source and the wavelength, and this relationship is defined by the Planck black body equation:

$$B = \frac{2hc^2}{\lambda^5} \frac{1}{e^{hc/kT} - 1} \quad (9)$$

where B = spectral radiance in $\text{J/s m}^2 \text{ nm sr}$; h = Planck's constant, $6.6262 \times 10^{-34} \text{ J/s}$; c = velocity of light in a vacuum, $2.99792 \times 10^8 \text{ m/s}$; λ = wavelength in nanometers; k = Boltzmann's constant, $1.38066 \times 10^{-23} \text{ J/K}$; and T = absolute temperature in Kelvin.

A typical 500 W tungsten lamp operates at 3000 K with an emissivity of 0.4. If the spectral radiance is plotted against wavelength, the spectral radiance will have a maximum at approximately 1000 nm and swiftly drops at approximately 300 and 5000 nm, so that the tungsten lamp is most useful in the visible and near-infrared range.

Incandescent lamps are not sufficiently intense to be useful in luminescence spectrometry, although their stability cannot be matched by gas discharge and arc lamps.

Discharge lamps involve the application of voltage across two electrodes in a gas or metal vapor consisting of neutral atoms and/or molecules. If free electrons are introduced (through a high-voltage spark), then electrons are accelerated and excited, producing light emission. Gas discharge lamps use hydrogen, nitrogen, and the inert gases. Metal vapor discharge lamps use the more volatile metals such as mercury, cadmium, zinc, gallium, indium, and thallium.

With an increased voltage across the gap, higher states of excitation occur, and radiation at shorter wavelengths is emitted. When the voltage exceeds the ionization potential, the gas will be ionized by collisions resulting in increased current such that protons are accelerated to the cathode and electrons to the anode. The reformation of protonated gas atoms or molecules is very improbable at low pressures and currents because secondary electrons generated as ions may strike the cathode, neutralizing the protonated gas atom or molecule. When the secondary electrons are sufficient to maintain the discharge current, a glow discharge occurs. When the current is further increased, the cross-sectional area of the discharge increases proportionally, and the voltage becomes constant. To increase the current further, the voltage must be increased, resulting in increased brightness with a change to an arc discharge where a voltage drop occurs. A contraction in discharge into a smaller area on the cathode may also follow.

Depending on the pressure in the lamp, both line and continuum emission may be observed. Low-pressure lamps operated at low current densities and temperatures produce sharp atomic lines with little or no continuous background. Increasing pressure and temperature cause the lines to broaden and increase the intensity of the background continuum.

High-pressure xenon, mercury, or mercury–xenon arc lamps are the most common excitation sources because of

their relatively high intensity, wide spectral range, and low cost. Commercially available xenon lamps are available in a wide range of power ratings and are usually operated on DC for greatest stability and longest life. Below 300 nm, the light output of the xenon lamp falls off sharply, such that the long wavelength peaks of the excitation spectrum are exaggerated and appear different from those in the absorption spectrum. Mercury–xenon lamps produce very intense light corresponding to the line emission spectrum of mercury (principal lines are at 254, 313, and 365 nm), and generally the light produced is more intense than that produced at any given wavelength by a xenon lamp of comparable power rating. However, these lamps emit very little light at other wavelengths, limiting the choice of excitation wavelength that may be used. However, because many substances have absorption spectra that overlap the mercury emission lines, they may be excited using the mercury–xenon lamp.

Pulsed discharge lamp (flash lamps) are used when high-intensity, short-lived pulses of exciting light are needed. A high-voltage capacitor is discharged across the gap, causing a short, high-current pulse to the lamp, and producing a very intense pulse of light.

The energy input to the lamp per flash is characteristic of lamp manufacture and is related to the capacitance and the voltage across the lamp:

$$Q = CV^2 \quad (10)$$

where Q = energy input in joules; C = capacitance in farads; and V = operating potential in volts.

The duration of the light flash is approximately equal to the duration of the current pulse through the lamp:

$$t_f = 1/2 R_a C \quad (11)$$

where t_f = flash duration in seconds, and R_a = effective arc resistance in ohms.

The effective arc resistance is proportional to the arc gap length and is inversely related to the 2/3 power of the operating voltage. This implies that the shortest, most intense pulses are obtained from lamps with very short gap tubes that are operated under high voltage and low capacitance. The value of R_a for a particular lamp is given by the manufacturer and is specific for a set of conditions.

The peak input power per flash in watts is given by:

$$P_i = Q/t_f \quad (12)$$

and the peak light output per flash in watts is:

$$P_0 = \varepsilon P_i \quad (13)$$

where ε = efficiency of conversion (usually 0.25–0.5 for xenon lamps).

The average input electrical power in watts is:

$$\bar{P}_i = Qf \quad (14)$$

where f = repetition rate in hertz.

The manufacturer generally recommends the maximum P_i value; higher-powered types may need to be forced air-cooled.

The average current drawn from the power supply is given by:

$$\bar{i} = VCf \quad (15)$$

The value of f should not exceed approximately $0.1 t_f^{-1}$ to prevent continuous ionization of the lamp.

The charging resistance R_c is selected so that its power rating is greater than the average input electrical power.

$$R_c = \frac{1}{5RC} \quad (16)$$

Xenon, nitrogen, and hydrogen flash lamps are available. The nature and pressure of the fill-gas affect the spectral distribution of the flash lamp.

The arc may appear narrow and filamentary when a xenon flash tube is operated below its maximum input power per flash because not all of the gas is ionized. The position of the arc tends to shift from flash to flash, causing erratic light output. It is generally not advisable to operate a flash tube very far below its maximum input.

Line sources

Glow discharge lamps (hollow cathode lamps) producing line spectra are quite similar to those propagating

Fig. 2 Schematic diagram of a hollow cathode lamp.

Fig. 3 Schematic diagram of an electrodeless discharge lamp.

continuous spectra presented above. Accelerated electrons generate positive ions on collision with atoms of a carrier gas (Fig. 2). The ions gain energy in an electric field and collide with the cathode. Atoms of the cathode are released and are excited by inelastic collisions with the electrons. The excited metal atoms then emit light.

The lamps are usually sealed and may have auxiliary electrodes to excite atomic vapor. They are operated at DC but may be modulated and pulsed. If the primary current i_p introduced is too high, the lines emitted are self-reversed. However, this may be avoided by keeping i_p low and i_a (auxiliary current) high.

Electrodeless discharge lamps, or EDLs (Fig. 3), are easy to make, but the results obtained are not always reproducible owing to chemical effects with the walls of the lamp, poor outgassing, poor seal-off, etc. A tesla coil starter produces a few free electrons that are accelerated by a high-frequency electric field (through the use of radio- or microwaves). The electrons acquire enough energy to excite and ionize atoms produced by the thermal heating. The actual discharge is confined to a "skin effect," wherein the outer surface of the envelope minimizes self-reversal. Low pressures (0.1–1 torr) of argon or neon gas are used; helium is usually not used because it diffuses out of the quartz envelope and is not very stable in intensity.

The lamps may be operated as continuous wave sources or be modulated or pulsed. EDLs have a poor stability or poor shelf life in some cases, but they have high intensities, produce narrow spectral lines, and are relatively inexpensive.

Lasers

Modern tunable dye lasers have any of several advantages over conventional sources, including 1) extremely narrow linewidths, 2) high intensity, 3) collimation and excellent

Fig. 4 Laser with conventional two-mirror cavity.

focusing abilities, 4) continuous tunability over certain wavelength regions, and 5) extremely short pulse duration. The primary disadvantages are their expense, relative complexity, and the difficulty to obtain wavelength-tunable laser output at wavelengths below 320 nm (nonlinear frequency mixing techniques may be used).

Lasers have three primary components (Fig. 4): 1) an active medium that amplifies incident electromotive waves, 2) an energy pump that selectively pumps energy into the active medium to populate selected levels and to achieve population inversion, and 3) an optical resonator, or cavity, composed of two opposite mirrors a set distance apart that store part of induced emission concentrated in a few resonator modes. A population inversion must be produced in the laser medium, deviating from the Boltzman distribution; thus, the induced emission rate exceeds the absorption rate, and an electromotive wave passing through the active medium is amplified rather than attenuated. The optical resonator causes selective feedback of radiation emitted from the excited species in the active medium. Above a pump threshold, feedback converts the laser amplifier to an oscillator, resulting in emission in several modes.

The wavelength range over which the laser would operate depends on the spectral range over which the active medium and cavity have a net gain. Wavelength selection devices such as gratings, prisms, and etalons are placed in the cavity when restricting the lasing wavelength is desired; these reduce the gain of the cavity below lasing threshold for all the desired wavelengths.

The active medium in tunable dye lasers is a dye solution. The dyes are organic compounds with conjugated double bonds and have delocalized π electrons that can

produce large absorption cross-sections. Because of the large dipole moments that can be generated, the spontaneous lifetime is short (<10 ns), and the quantum yield of fluorescence is large. Dye lasers are pumped by flashlamps, N_2 lasers, Cu vapor lasers, Nd-YAG, excimer, or Argon ion lasers. They oscillate within a broad band. Therefore, short pulses can be obtained.

Semiconductor lasers (laser diodes) have recently appeared as luminescence excitation sources. They have several outstanding advantages over gas and dye lasers and arc lamps as excitation sources. They are more powerful and more coherent light sources than arc lamps. They also have the advantage of producing a polarized beam that can be useful for certain applications. They are smaller, more compact, and much less expensive than other kinds of lasers, and the fact that most semiconductor lasers emit in the far-red or infrared means that less energy can be deposited in the sample so that considerably less thermal decomposition can occur than with conventional ion, excimer, and dye lasers. That until recently, emission from semiconductor lasers has been generally confined to the far-red and infrared has been a mixed blessing. On the one hand, the fact that so few substances demonstrate electronic absorption in that region of the electronic spectrum means that excitation with semiconductor laser light will be very selective. For example, the interfering luminescences of tryptophan and bilirubin from serum samples will not be problematic with semiconductor laser excitation because these substances are not excited by red light. On the other hand, because so few substances absorb red light, a new generation of fluorescent probes and labels is required for the labeling of analytes to be detected subsequent to chromatographic or immunochemical analysis.

Several of the polymethine dyes absorb in the red, far-red, and near-infrared and fluoresce efficiently as well in this spectroscopic region. Functional derivatives of these may provide excellent fluorescent labels for semiconductor laser excitation. Several research groups are currently actively involved in the synthesis and development of large polyunsaturated dye molecules that are excited and show luminescence in the red and near-infrared. This promises to be one of the most exciting areas of luminescence spectroscopy for the foreseeable future.

Wavelength Selection

The choice of limited spectral wavelength bands for excitation and emission is necessary to prevent the possibility of excitation and detection of emission from extraneous species and to spurious stray light. Mono-

chromators and filters are used to select the wavelength areas of interest.

Filters

Filters are absorption type, made of tinted glass, gelatin-containing organic dyes lacquered or sandwiched between glass, or a solution of absorbing substances, or are interference filters.

Absorption filters selectively absorb portions of incident polychromatic light and allow the transmission of light of preferred wavelengths. There are three general classifications: 1) neutral tint, 2) cut-off filters, and 3) bandpass filters. Neutral tint or neutral-density filters have a nearly constant transmission over a range of wavelengths; they are used with strongly fluorescing compounds and decrease light intensity uniformly. Cut-off filters have a sharp cut-off in their transmittance characteristics; beyond a certain wavelength there is little or no transmittance. These are especially useful in preventing stray or unwanted light from falling on the detector. Bandpass filters either transmit or refuse a set wavelength band and are usually made from a series of cut-off filters.

An interference filter consists of two highly reflective but partially transmitting films of silver separated by a spacer film of completely transparent material (e.g., MgF_2). Light of wavelength corresponding to the optical separation of the silver films (± 5 – 9 nm), and integral multiples of this principal wavelength, are transmitted, whereas other wavelengths are eliminated by destructive interference. These filters are suited for intense sources because they absorb very little energy and rarely need to be cooled.

Monochromators

Monochromators are usually diffraction gratings with slit arrangements. Prisms were once used as monochromators but are now almost obsolete because gratings are much less expensive and less cumbersome. Polychromatic light is dispersed by the grating into its component wavelengths through constructive and destructive interference. Two types of gratings are available: transmission and reflection gratings.

A large number of parallel transparent and opaque lines are arranged alternately on a transmission grating; when a source is incident on one side of the grating, each transparent line acts as an independent line source of the original radiation. Interference will occur among the monochromatic light waves transmitted by the closely spaced transparent lines, causing an augmentation in light intensity at certain points and elimination at others.

Fig. 5 Diffraction grating. Ng = normal to the grating; Nf = normal to the face of the grating; A = angle of incidence; Θ = angle of diffraction; d = grating spacing; and B = blaze angle.

A reflection grating is similar to a transmission grating except that it uses a large number of grooves on a reflective surface to cause the interference.

Fig. 5 shows a parallel light beam incident onto two adjacent grooves of a diffraction grating. At a wavelength and an angle of incidence A normal to the grating surface, constructive interference for an angle B is obtained:

$$m\lambda = d(\sin A \pm \sin B) \quad (17)$$

where m = order of interference.

The plus sign is taken if A and B are on the same side of the grating normal and the minus sign if they are not. If the light is reflected back into the direction of the incident light, the equation reduces to:

$$m\lambda = 2d \sin B \quad (18)$$

When $m = 0$, the angle of the incident radiation is equal to the angle of diffraction, and this corresponds to specular reflection of the incident radiation. When $m = 1$, the diffraction is said to be first-order and is the primary image of the spectrum. When $m = 2$, the diffraction is second-order and is the second image of the spectrum with a dispersion twice that of the first-order, and so forth for higher orders. This may cause interference. Therefore, a filter is used to eliminate higher-order spectra.

Two important factors in selecting a grating are its blaze angle and resolving power. The blaze angle ϵ is dependent on the blaze wavelength. The output of a grating at a particular wavelength is compared with that of an aluminum mirror, and the blaze corresponds to the

wavelength of maximum efficiency:

$$\Theta = \frac{A - B}{2} \quad (19)$$

A is fixed by the construction of the instrument, whereas B varies with A according to Eq. (17). The resolving power R depends on the number of grooves in the grating N and the order of interference:

$$R = mN \quad (20)$$

R is relatively independent of wavelength. A grating with a high resolution would produce better separation of the polychromatic light to its component wavelengths.

The excitation grating is on a turntable that when rotated allows light of different wavelengths to be focused through a slit and onto the sample. The sample would fluoresce, and the light would be channeled by the emission grating, which is also on a turntable, and is focused through another slit onto the detector.

Slits

Slits help focus light onto the monochromators and the detector; they regulate the wavelength range that excites and is emitted by the sample. Smaller slit widths are more selective, producing a narrower range of spectral bandpass (bandwidth at half the peak transmittance), but a decrease in transmitted light is noted and, therefore, there is a decrease in sensitivity. There are two types of slits: fixed and variable.

Fixed slits are cut in an opaque material. A series of these are found in instruments using fixed slits; the desired slit width is obtained by using any one in the group, and the results so obtained are reproducible.

Variable slits are used more commonly than fixed slits. There are two types available: unilateral or bilateral. Both involve the use of beveled blades attached to micrometers that allow the blades to shift a specified distance, although unilateral slits have only one movable blade; the other is fixed. Bilateral slits are preferred over unilateral slits because a constant center line is maintained with the former whereas that using the latter continuously changes as the slit width changes. Variable slits are more expensive but are more convenient for routine analysis. With constant use, the micrometer mechanism and blade edges become worn, resulting in a decrease in sensitivity and reproducibility. This is not considered a major problem in analytical work unless a precise knowledge of the slit widths is imperative.

Cell Compartments and Cells

Cell compartments are usually painted flat black to minimize stray light and are covered when the fluorimeter is in use to eliminate the entrance of external light. They are usually set such that the fluorescence emitted by the sample would be at a 90° angle to the line of entry of the exciting light. This arrangement decreases the interference of stray exciting light. If the sample has strong absorption at the excitation wavelength or is a solid, concentration quenching may occur, especially if the sample has a low quantum yield. Using a front-surface configuration, with the fluorescence emitted at 30° to the line of entry of the exciting light, may solve this problem. Solid sample holders with glass, quartz, or silica windows are also available.

Fluorescence cells are made of quartz, silica, or special optical glass. Glass cells are cheaper and are suitable for use with excitation wavelengths above 330 nm. For shorter wavelengths, quartz or silica cells have to be used. If analysis is to be performed at low temperatures, cryorefrigerators or Dewar flasks (Fig. 6) are used.

Fig. 6 Dewar flask.

At low temperatures, both fluorescence and phosphorescence may be detected when the sample in the Dewar flask is illuminated. If only phosphorescence is emitted by the sample, this setup may be used to measure phosphorescence. To isolate phosphorescence when both types of luminescence are present, a mechanical chopper with openings 180° apart is mounted in the sample compartment and rotated at a speed of several thousand revolutions per minute. This effectively cuts off the fluorescence because its lifetime is 10^{-11} – 10^{-7} s, and the emitted light would have vanished completely in one quarter of a revolution. Phosphorescence has a longer lifetime (10^{-4} to several seconds) and will be registered by the detector.

Detectors

Photomultipliers

Photomultipliers are the most widely used photodetectors in fluorescence spectroscopy. They detect very low levels of light using secondary emission from a dynode chain (Fig. 7). A photomultiplier is made up of an evacuated glass or quartz tube containing a photocathode, a series of dynodes made of electron emissive material, and an anode. Fluorescence emitted by the sample strikes the photocathode, which in turn emits photoelectrons. These electrons are accelerated toward the first dynode, and more electrons are produced, hitting the second dynode and producing even more electrons, and so forth, until the last dynode, when electrons coming from the last dynode strike the anode. The anode current flows through the load resistor, generating the signal voltage.

The amplification factor of the photomultiplier G depends on the electron gain per dynode g and the number of dynodes x :

$$G = g^x \quad (21)$$

Fig. 7 Photomultiplier.

The amplification and gain per dynode of an amplifier rely on the operating voltage. Thus, photomultipliers need a very stable high-voltage power supply. The spectral response depends on the cathode type and envelope material and is not affected by the electron multiplication process.

At room temperature, the noise in photomultipliers is predominantly shot noise, which is because of the fundamentally quantized nature of light energy and electrical current. Photons arrive at the cathode randomly, even though the overall intensity of light is constant. Photoelectrons emitted from the cathode arriving at the anode would thus do so randomly, even though the long-term rate of photoelectron pulses is constant and parallel to the light intensity:

$$i_s = \sqrt{2eBG\Delta f i_a} \quad (22)$$

where $B = 1 + g^{-1} + g^{-2} + \dots + g^{-Z} = \sum_{y=0}^Z g^{-y}$ and f = electrical noise bandwidth in hertz.

The equation for shot noise current i_s owing to the total anodic current (photocurrent plus thermionic current) i_a takes into consideration the gain of the tube G . Shot noise may often be reduced by increasing the measurement time because this would increase the signal-to-noise ratio. The thermionic component of the noise may be reduced by cooling the tube. There is a minimum temperature to which the tube may be cooled. Exposure of the tube to high light levels may cause changes in the sensitivity of the tube, and photomultipliers must never be exposed to room light or irreversible damage may result. A fatigued tube may often be restored by operating it in the dark for some time at the normal operating voltage. The cathode or anode currents must not exceed the ratings specified by the manufacturer. Photomultipliers usually have a response time of less than 10^{-8} s, which is rapid enough to detect most fluorescence decay-times.

Fig. 8 Photoconductive target vidicon.

Fig. 9 Return beam vidicon.

Image detectors

Vidicons are of two types: the photoconductive target vidicon (1) and the image orthicon, or return beam vidicon (2). In the former (Fig. 8), light incident on a target previously biased by an electron beam would cause a charge separation in the photosensitive material. The carriers of the charge discharge the bias proportionate to the amount of light striking each local area, or pixel. When the raster-scanned beam returns to this region, it replaces the bias, and a signal is detected as the voltage across the load resistor is detected. The illuminated pixels cause an increase in the signal.

The return beam vidicon (Fig. 9) uses a photocathode to detect the light image. The photoelectrons are formed on a target composed of a secondary electron emitter similar to the dynodes in a photomultiplier, and secondary electrons produced are collected by a mesh, leaving the target with an image stored in the form of positively charged areas corresponding to the lit parts of the photocathode image. A low-velocity electron beam scans the target surface, and electrons are absorbed from the beam where the target is charged; the beam is scattered only in areas of little or no charge. An anode finally collects the scattered electrons. Unlike the photoconductive target vidicon, illuminated areas in the image orthicon cause a decrease in signal current.

Intensified vidicons (Fig. 10) detect photoelectrons instead of photons. There are two groups: in SEC vidicons, the target is a secondary electron conductor such as MgO, KCl, MgF, and Ag, whereas silicon-intensified target (SIT) vidicons have silicon diode arrays as their targets. SEC vidicons are approximately 10 times more sensitive

Fig. 10 Intensified target vidicon.

than ordinary vidicons, and SIT vidicons are up to 500 times more sensitive: they are capable of single-photon detection (3). The use of the latter is limited by its high noise level; however, cooling the tube and shutting the readout beam off can lower the noise by increasing the integration time (4).

Charge-coupled devices (CCD)

CCD sensors provide a higher sensitivity to light than do common detectors and photographic film, allowing for the acquisition of weaker signals. This technology has revolutionized the use of fluorescent microscopes in the biomedical sciences and has begun to have an impact on fluorescent-based analytical systems.

A CCD chip is an array of light-sensitive elements that are in fact small electronic capacitors. These capacitors are charged by the electrons generated by the emitted light. In fact, each photon that reaches the CCD array's atoms displaces some electrons that are providing a current source. These current sources are localized in small, delimited areas (the capacitors) called pixels.

Common CCD chips are composed of several pixels, for example, 192×165 , 512×512 , 1024×1024 , or more. It is easy to understand that it is physically impossible to individually access each pixel. In fact, a CCD sensor provides only one serial output, through which each capacitor can be discharged (each pixel can be read). The capacitors are disposed in lines, and there are some control gates that allow the transfer of one pixel line into the next. The last line of the array can be transferred into a horizontal shift register. This shift register allows the transfer of one pixel to the next, and the last pixel of this horizontal register is connected to the output gate.

The CCD chip has one clock entry for the vertical transfer, one for the transfer gate, and one for the shift register. Thus, read out the signal, one must first transfer

the last line into the shift register by providing a clock pulse on the transfer gate control pin. Then one has to provide one clock pulse on the shift register control pin for the reading of each point of this line. Finally, one must provide one clock pulse on the vertical transfer. The high number of pixels allows increases sensitivity and spatial resolution.

If a CCD array is used in a warm environment (20°C), the photosensitive area atoms produce a current, which produces noise. To reduce this noise, the CCD array atoms should be cooled so that their thermal excitation is reduced. The CCD is cooled by two primary processes: 1) electrical and 2) chemical.

Cooling a CCD by use of liquified gas is most efficient but is still reserved for the highest sensitivity purposes. This is primarily owing to the equipment needed to store and use such liquids. Thus, the most commonly used process is the use of a thermoelectric cooler, also known as a Peltier cell. It is a device working as a heat pump. The heat contained in one face of the cells is transferred to the other. These cells should be powered by direct current. Efficiency improvement of such a cell can be performed by cooling its hot face. To provide substantial cooling of the CCD, it is possible to use two Peltier cells in addition to a water- or glycol-cooling system. The first cell cools down the CCD, the second cools the first, and the liquid circuit evacuates the heat provided by the second Peltier cell.

Signal Processing

These systems amplify and process the electrical signal from the detector and show it in a read-out form. The electrical noise bandwidth is usually determined by the system, which in turn influences the amount of noise of the signal and determines the response time of the system.

DC amplifiers

DC amplifiers are the simplest and least expensive of the electronic measurement systems. They are most commonly found in commercially available fluorimeters. Ideally, the amplifier stage of a circuit contributes little or no noise to the system; the photomultiplier should produce only the noise associated with perfect performance of the photocathode and the electron multiplication process described above. However, the anode dark current of the photomultiplier adds to the noise in the signal, and the amplifier makes its own contribution to the total noise. It is therefore imperative to select the proper photomultiplier tube with low dark current so as to have a higher signal-to-noise ratio.

Photon counting

The current pulse from a single photon event would be noted at the anode as an approximate million electrons and a pulse width in nanoseconds. The amplifier changes the anode current pulse into a pair of voltage signals with sufficient gain and output impedance to couple it to the discriminator, which then shapes the pulse and rejects those below a set minimum threshold. The maximum count rate of less than 10^7 pulses/s determined by the pulse pair resolution of the amplifier-discriminator limits pulse counting, but methods to increase the upper limit by multilevel discrimination (5) and DC switching at high light levels (6) have been described.

Correction of Spectra

Excitation and emission spectra obtained from most instruments are dependent on the wavelength-sensitive components of the particular system. To compensate for these and the different amounts of light loss per instrument, corrections for instrumental characteristics are necessary to obtain the true spectra. The results allow intrainstrument spectral comparisons to be made. Although self-correcting instruments are commercially available, these are generally too complicated and expensive for routine analytical work.

Excitation spectra may be corrected using a constant response thermopile, a chemical actinometer, a standardized phototube, or a reference compound. The latter two methods also may be used for correcting emission spectra. By reporting fluorescence intensities in relation to reference compounds, one guards against the source and photomultiplier aging characteristics of a given instrument. Any stable fluorescent compound with broad excitation and emission bands is suitable for this purpose.

SPECIAL TOPICS

The following spectroscopic topics are viewed as current areas of analytical interest. Many review articles give a more thorough discussion of these subjects, and these are cited accordingly.

Chemiluminescence

Fluorescence initiated by chemical reactions is called chemiluminescence. It is a common phenomenon in flames in which free radicals are oxidized by molecular

oxygen but occurs rarely in solution because many of the reactive species necessary for the generation of chemiluminescence have very short lifetimes in solution. Phosphorescence as a form of chemiluminescence does not exist in solution because of quenching of the triplet state in the liquid phase.

A number of chemiluminescent reactions are known. The oxidation of 3-aminophthalhydrazide (luminol) has been studied extensively (7–14). The emission resulting from the reaction of certain oxalic acid derivatives is another outstanding example (15). When chemiluminescence occurs in living organisms, it is called bioluminescence. The best known example is observed in the firefly *Photinus pyralis*. Many review articles have been written about different aspects of bioluminescence; for overviews one should consult those by Gundermann and McCapra (16) and by Campbell (17).

Because chemiluminescence does not require photoexcitation, a lamp and excitation monochromator are unnecessary. Conventional fluorometric spectrophotometers may be used to measure chemiluminescence except that the excitation optics are not used.

Fiber Optic Sensors

The fiber optic fluorometer is a recent development that shows great promise for in situ fluorometry. In this device, the sample compound and cell are replaced by a fiber optic cable. Light from a source travels along an optically conducting fiber to its end where absorption, reflection, or scattering of light or fluorescence occurs. Fluorescence sensors comprise the largest group of fiber optic sensors; fluorescence sensors based on principles of direct fluorescence measurement, both single- and dual-wavelength (18, 19), fluorescence quenching (20, 21), or competitive binding (22) are available. Owing to the paucity of directly fluorescent analytes, most fluorescent optical sensors (FLOPS) are based on quenching by the analyte of the sensor fluorophore.

Instrumentation essentially consists of a light source, optical filters (if necessary), the fiber optic, a sensing zone (to which a fluorescent probe is usually covalently bound), and a detector. Lasers; xenon lamps; hydrogen-, deuterium-, mercury-, and halogen lamps; and light-emitting diodes (LEDs) have been used as excitation sources. Lasers provide high-intensity excitation with a narrow bandwidth and are especially suited for remote sensing where light losses are large. However, they are quite expensive and require a heavy power supply. The most promising light sources are the LEDs; these run at a low voltage and current, are small, have long life spans,

and do not generate heat. However, they do have the disadvantage of working only from the IR region down to the blue. Fiber optic fluorescence spectrometers may be operated in a continuous or pulsed excitation mode. The latter allows for the application of time-resolved fluorimetry. The material of the optical fiber would determine the wavelength used. Fused silica, glass, and plastic fibers have all been used. Silica can be used from the ultraviolet range down to 220 nm, but the fibers are expensive. Glass is suitable for use in the visible region and is reasonably priced. Plastic fibers are the lowest in cost but are limited to use above 450 nm. Measurements may be processed directly using analog and digital circuits or a microprocessor. Photomultipliers, photodiodes, photoconductor cells, photovoltaic light detectors, and CCDs have all been used as detectors.

Fiber optic sensors are less expensive, more rugged, and smaller than electrodes, which currently dominate in sensor-based analysis. In the future, we may see the former replacing the latter in various areas of analytical and clinical chemistry. Fields of application include groundwater and pollution monitoring; process control; remote spectroscopy in high-risk areas with radioactive, explosive, biological, or other hazards; titrimetry; and biosensing. Different aspects of optical sensing have been the subject of several studies (23–25). The field of FLOPS is currently one of the most active in analytical spectroscopy.

Luminescence Detection in Separation Methods

A limitation of the application of luminescence spectroscopy to the analysis of real samples is its lack of specificity owing to similarities in spectral bandshapes and spectral positions of the luminescence spectra of many compounds. An obvious solution to this problem is the separation of the analytical sample's interfering constituents from each other before quantitation by fluorescence. High-performance liquid chromatography (HPLC) and related separation methods can be coupled to fluorescence spectroscopy to take advantage of the sensitivity of the spectroscopic method and the specificity of the separation method.

Luminescence affords a very sensitive means of detection in flowing systems such as HPLC, electrophoresis, flow injection, and flow cytometry. HPLC fluorescence detectors are similar in operation to conventional fluorimeters. Most fluorescence detectors use filters for crude monochromation. Filters pass light in a wider band than do monochromators. This favors spectral sensitivity because more light excites the sample and is collected by the detector. Grating monochromators, on the other hand,

favor selectivity. The fluorimetric detector is susceptible to the usual interferences that hinder fluorescence measurements, namely, background fluorescence and quenching.

In the operation of a fluorimetric HPLC detector, the light from a UV or visible source is monochromated to some degree and focused on the cell that is on line with and receiving the effluent of the separatory column. Fluorescence is emitted by the sample in all directions so that the emitted light can be measured with the detector at right angles to the path of the exciting light and the direction of fluid flow. Stray or scattered excitation light is then blocked from the detector by a filter, and the emitted energy is then measured using a suitable detector. It is important to recognize that the solvent has a strong effect on the intensity of fluorescence. The solvent also scatters light owing to the Raman effect. This light is of slightly lower energy than the exciting light. For this reason, the emission wavelength is selected to be longer than that of the scattered Raman light. Flow cells have been designed that can be used for both fluorescence and absorption measurements. Quantitation can be considerably improved by simultaneously monitoring the absorbance and fluorescence signals that extend the linear dynamic range for fluorescent samples. At high sample concentrations in which the absorbance at the excitation wavelength is greater than 0.02, fluorescence intensity becomes non-linear with concentration. At these higher concentrations, however, the light absorbance of the sample is often measurable and linear with concentration. Fluorescence, however, is often detectable at concentrations from 10^3 to 10^9 times lower than those in which absorbance is detectable.

The laser as an excitation source for luminescence detection in chromatography has become popular because of its high excitation power and its highly focused beam. The high degree of collimation of the laser beam has made it an excellent excitation source with the microbore cells, and tubing used is capillary zone electrophoresis. A typical laser beam can be focused into a spot a few microns in diameter. With laser excitation and fluorescence detected, capillary zone electrophoresis analyte concentrations below 1 attomole (at nanomole concentrations) have been measured. The advantages offered by the power and high degree of collimation of the laser as an excitation source can be exploited to measure the properties of a variety of particles including cells, algae, bacteria, larvae, etc., that either show native fluorescence or can form fluorescent adducts. A well-defined flow of isolated particles is achieved by using hydrodynamic focusing. The particle flux is interrogated by a laser beam, which excited one particle at a time. Single-cell passage is guaranteed by adjusting the two flows; thus, collision between two cells

(particles) is avoided. The method allows high-speed analysis of the cells and is called flow cytometry or fluorescent cell-sorting.

Time and Phase-Resolved Fluorimetry

The spectroscopy described thus far is based on the measurement of the intensity of fluorescence produced under steady-state conditions of excitation. Steady-state fluorimetry is derived from the excitation of the sample with a continuous beam of exciting radiation. The lamps and the power supplies used in conventional fluorimeters are sources of continuous radiation. After a short period of initial excitation of the sample, a steady state is established in which the rate of excitation of the analyte is equal to the sum of the rates of all processed, deactivating the lowest excited singlet state including fluorescence. When the steady state is established, the observed fluorescence intensity becomes time-invariant and produces the temporally constant signal that is measured by the photodetector. With the development of modern electro-optical components, it has become possible to excite a potentially fluorescent sample with a pulsed flash lamp that emits its radiation in bursts of 2–10 ns in duration with approximately 0.2 ms between pulses. Pulsed lasers generate even shorter duration pulses (typically down to 1 ps). A fluorescent sample excited by a single pulse will decay exponentially until the next pulse again excites the sample. The fluorescence from the sample excited by the pulsed source can be represented, after detection, as a function of time on a fast sampling oscilloscope used in conjunction with a multichannel pulse analyzer. The former approach is called pulse fluorimetry and the latter time-correlated single-photon counting. In either case, fluorescences with decay-times much longer than the lamp-pulse characteristics can be analyzed from a semilogarithmic plot of fluorescence intensity against time, which will yield a straight line (or a series of overlapping lines if several fluorophores have comparable but not identical decay-times) whose slope is proportional to the decay-time and whose vertical axis intercept can be compared with that of a standard solution of the fluorophore for quantitative analysis. If, however, the lamp pulse-time and the decay-time of the fluorophore are comparable, the lamp characteristics must be subtracted from the observed signal to obtain the fluorophore's decay characteristics. This is usually accomplished by using a computer to deconvolute the composite temporal characteristics of the lamp and the fluorophore output.

The pulsed source (time-resolved) method then distinguishes between the emissions of several fluorescing

species by using their decay-times rather than their fluorescence intensities. This means that several strongly overlapping fluorescences such as those of catecholamines can be quantitated simultaneously without chemical or mechanical separation.

Time-resolved fluorimetry is also useful for the elimination of interferences from stray light caused by Rayleigh and Raman scatter. The latter phenomena occur on a time scale of 10^{-14} – 10^{-13} because they have a much shorter duration than lamp or laser pulses. This light associated with them can be eliminated from the signal that ultimately reaches the detector. Data taken on one time-resolved fluorometer can be directly compared with that from another. This is not possible in steady-state fluorimetry unless correcting wavelength variable instrumental response has been affected.

Phase fluorimetry is another useful fluorimetric technique for the determination of substances with overlapping fluorescence spectra. In phase fluorometry, the phase angle between the lamp pulse and the emission of fluorescent light allows for discrimination between fluorescences of different origin. For additional reading on this subject, see the excellent review by Demas (26).

With the introduction of powerful computers and advanced programs, traditional fluorescent devices are pushing the fringes of detection. It is now possible to observe events at a single molecule level. Information from these studies is refining our understanding of biochemistry and cell trafficking of molecules (28).

SPECTROSCOPIC METHODS OF ANALYSIS—INFRARED SPECTROSCOPY

Marilyn D. Duerst

University of Wisconsin-River Falls, River Falls, Wisconsin, U.S.A.

INTRODUCTION

Infrared (IR) spectroscopy refers broadly to the study of the interaction between matter and infrared radiation. Infrared radiation falls in the region between the visible and microwave parts of the electromagnetic spectrum, with wavelengths from 0.7 to 500 μm . Infrared spectroscopists often express this region of the spectrum in units of wavenumbers (symbol cm^{-1}) which refers to the number of waves per centimeter. This region (14,000 to 20 cm^{-1}) is usually subdivided into three regions: from 14,000 to 4000 cm^{-1} is called “near-infrared,” from 4000 to 400 cm^{-1} the “mid-infrared,” and from 400 to 20 cm^{-1} the “far-infrared.” The mid-infrared region is widely used in the analysis of drugs and pesticides, and will be the focus of discussion here.

Chemical compounds absorb infrared radiation when there is a dipole moment change (in direction and/or magnitude) during a molecular vibration, molecular rotation, or molecular rotation-vibration. Absorptions are also observed with combinations, differences or overtones of molecular vibrations. A specific type of molecule is limited in the number of vibrations and rotations it is allowed to undergo. Therefore, each chemical compound has its own specific set of absorption frequencies and thus exhibits its own characteristic IR spectrum. This unique property of a compound allows the organic chemist to identify and quantify an unknown sample. (A special infrared technique called vibrational circular dichroism (VCD) is required to distinguish optical isomers).

Certain functional groups in a molecule (e.g., hydroxyl, carbonyl, and amine) absorb IR radiation and exhibit absorption bands at characteristic frequencies regardless of the structure of the rest of the molecule. These bands are termed “group frequencies.” They are predictable and allow the analyst to deduce important structural information about an unknown molecule. An IR spectrum can be rapidly recorded for any phase, i.e. solid, liquid, or vapor. By coupling IR spectroscopy with other analytical techniques such as nuclear magnetic resonance (NMR) spectroscopy and mass spectrometry, the organic

chemist can determine the structure of an unknown compound.

The introduction of the Fourier transform infrared (FTIR) spectrometer has revolutionized the entire field of IR spectroscopy. The typical FTIR spectrometer has a number of advantages over the conventional dispersive IR spectrometer in terms of the resolution of bands in the spectrum and the speed of acquiring the spectrum. Because of continuous improvements in sampling techniques, analysis software, and instrumentation hardware, the FTIR spectrometer has become increasingly more valuable in many areas from fundamental research to quality control to on-line process control. Recently, much interest has been focused on coupling the FTIR spectroscopic technique with chromatographic and other analytical techniques such as gas chromatography (GC-FTIR), GC-mass spectrometry (GC-MS-FTIR), high-performance liquid chromatography (HPLC-FTIR), supercritical fluid chromatography (SFC-FTIR), thin-layer chromatography (TLC-FTIR), and thermogravimetric analysis (TGA-FTIR). These methods, often termed “hyphenated techniques,” employ IR spectroscopy as a means of detection to identify an unknown substance in a chromatographic eluent. Used in conjunction with a proper interfacing and sampling techniques, the limit of detection in some studies can also be in the picogram range, especially with the FTIR microscope.

This general approach will discuss the fundamental principles, instrumentation, and current applications of IR spectroscopy. Numerous reference materials, covering all aspects of infrared spectroscopy, have been published over the years (1–3). For a more in-depth understanding of the theory and instrumentation, readers can refer to the bibliography and references listed at the end of this article.

THEORY

The electromagnetic spectrum includes radiation from cosmic rays to radio waves, with wavelengths ranging from 10^{-9} nm to longer than 1000 km. In progression from

short to long wavelengths, the types of radiation included in the spectrum are gamma rays, X-rays, far-, middle-, and near-ultraviolet rays, visible light, infrared rays, and microwaves.

Electromagnetic radiation may be conceptualized as a wave traveling at the speed of light (c) in a vacuum, where c is approximately 3.0×10^8 m/s. The frequency (ν) is related to the wavelength by Eq. 1.

$$c = \nu\lambda \quad (1)$$

The wavelength, in units of cm or μm , is defined as the distance between peaks or troughs of the wave. The frequency of the wave is the number of peaks passing a fixed point per unit of time. The unit of frequency is the Hertz, i.e., the cycles or waves per second.

In infrared spectroscopy, the wavenumber, $\bar{\nu}$, is often used instead of frequency, and is related to wavelength according to Eq. 2.

$$\bar{\nu} = 1/\lambda \quad (2)$$

The wavenumber, in units of cm^{-1} , is the number of waves per centimeter. It is directly proportional to the frequency, but is not the same as frequency, as shown in Eq. 3.

$$c = \nu\lambda, \text{ thus } \bar{\nu} = \nu/c \quad (3)$$

The relationship between wavenumber (in cm^{-1}) and wavelength (in μm) is given by Eq. 4.

$$\bar{\nu} = 10^4/\lambda \quad (4)$$

INFRARED SPECTROSCOPY

Electromagnetic radiation may also be considered as photons traveling at the speed of light. The energy of a photon (E) is related to the wavelength (λ), frequency (ν), and velocity of light (c) by Eq. 5, where h is Planck's constant ($h = 6.626 \times 10^{-34}$ J/s).

$$E = h\nu = hc/\lambda \quad (5)$$

In all spectroscopic techniques, the interaction of radiation with the molecule results in the transfer of energy to the molecule. The energy absorbed by the molecule is quantized, that is, the absorption is specific to the frequency of the radiation. Depending on the energy of the photons, the effect of an increase in energy in the molecule could cause reorientation of nuclear or electron spin states (if the molecule were in a magnetic field), changes in the energy of the valence electrons, changes in the vibrational-rotational energy, ejection of inner electrons from the molecule, or changes in the nucleus.

The absorption of IR radiation changes the rotational and/or vibrational energy states of the molecules. The IR absorption spectrum of a molecule may appear as a set of broad bands rather than discrete lines because each vibrational energy change is accompanied by a number of rotational energy changes. Three main types of absorption involving vibrations include the fundamental vibration, overtones, and combinations. The fundamental vibrational absorption bands usually appear in the mid-infrared region. It is important to realize that a molecule absorbs incident infrared radiation only when the molecular vibrational frequency is the same as the frequency of the incident radiation, and if the vibration of the atoms results in a change in the dipole moment. A symmetrical vibration does not result in a change of dipole moment; therefore, no infrared absorption will occur.

Two main types of fundamental vibrations are stretching and bending. Stretching vibrations usually appear at higher frequencies than bending vibrations. A stretching vibration consists of the movement of the atom along the bond axis, which results in changes in bond length. A bending vibration consists of a change in bond angles between bonds with a common atom. Fig. 1 shows the typical stretching and bending vibrational modes of a $-\text{CH}_2-$ group within a molecule.

The intensity of vibrational absorption is proportional to the square of the magnitude of the dipole moment change. For a small dipole-moment change, the absorption band is weak, whereas a large, permanent dipole moment, such as that in a carbonyl group, exhibits strong absorption in the infrared when the carbon-oxygen distance is changed.

The stretching frequency is affected by the masses of the atoms and the strength of the bonds (i.e., the "stiffness" of the chemical bond) connecting them. Their relationship can be approximated by Eq. 6.

$$\bar{\nu} = (1/2\pi c)(f/u)^{1/2} \quad (6)$$

where $\bar{\nu}$ is the vibrational frequency (cm^{-1}), c the velocity of light (cm/s), f the force constant of the bond (mN/m or dyn/cm), u the reduced mass of the two atoms, m_1 and m_2 , or $u = (m_1 m_2)/(m_1 + m_2)$.

The spatial orientation of atoms with respect to each other also affects their vibrational frequency. For example, the coupling or interaction of two fundamental vibration groups of similar frequencies in close proximity within a molecule and the inter- or intramolecular hydrogen bonding affect the vibrational frequencies of the molecule.

In general, the vibrational frequency is higher for atoms with a smaller reduced mass and a larger force constant. Vibrations of groups where one atom is hydrogen have a higher frequency than those with other, heavier atoms.

Fig. 1 Stretching and bending vibrations of a $\text{—CH}_2\text{—}$ group.

For example, if the hydrogen atom in the C—H group is replaced by a deuterium atom, the vibrational frequency of C—D is lower than the vibrational frequency of C—H by a factor of about 1.414. The force constant is proportional to the bond strength (and thus to the bond order) between atoms. Therefore, for groups with atoms of the same mass, the vibrational frequency for triple-bond groups is about three times higher than that for double-bond groups. The vibrational frequency for the double-bond group is twice as high as that for the single-bond group.

Absorption bands that are attributed to overtone and combination vibrations are also observed in the IR spectrum of polyatomic molecules. Overtone vibrations occur at frequencies of approximately integral multiples of the fundamental frequencies. Combination vibrations appear at frequencies that are the sum or the difference of the frequencies of two or more fundamental vibrations. Overtone and combination bands are much less intense than fundamental bands.

Fermi resonance, which is the interaction between fundamental vibrations and overtone or combination vibrations, is also common in IR spectra. The result of Fermi resonance is the formation of two new vibration modes with one frequency higher and the other one lower than that observed when the interaction is absent. The unique quality of an IR absorption spectrum for a molecule

is partly attributed to overtone bands, combination bands, and Fermi resonance bands.

INSTRUMENTATION

Two main classes of infrared instrumentation are dispersive and nondispersive. A dispersive instrument uses a prism or grating to separate light into its frequencies. An IR spectrum generated by a dispersive instrument is normally a plot of wavenumber (cm^{-1}) or wavelength (μm) versus percent transmittance. In a nondispersive instrument, the IR radiation does not pass through a prism or grating, but through an interference filter or an interferometer, as in a Fourier transform infrared spectrometer, and is then collectively sent through the sample. An interference pattern generated by absorption within the sample is called an interferogram. It can be converted into a conventional IR spectrum by application of a mathematical operation (the Fourier transform) to the data. Using modern computer technology, this mathematical manipulation can be completed in a matter of seconds.

A typical IR spectrometer consists of the following components: radiation source, sampling area, monochromator (in a dispersive instrument), an interference filter

or interferometer (in a nondispersive instrument), a detector, and a recorder or data-handling system. The instrumentation requirements for the mid-infrared, the far-infrared, and the near-infrared regions are different. Most commercial dispersive infrared spectrometers are designed to operate in the mid-infrared region ($4000\text{--}400\text{ cm}^{-1}$). An FTIR spectrometer with proper radiation sources and detectors can cover the entire IR region. In this section, the types of radiation sources, optical systems, and detectors used in the IR spectrometer are discussed.

RADIATION SOURCES

Infrared radiation is generated by electrically heating a source to a certain temperature. Several radiation sources (sometimes called “black body” sources) are commonly used for mid-infrared spectrometry. Table 1 summarizes the properties of each source, including the sources used for the near-IR and far-IR regions. Most sources have a maximum energy output at a certain wavelength range when heated at their optimum temperature. The energy of the radiation decreases gradually at longer wavelengths. In a dispersive instrument, however, widening the slit to allow more radiation to reach the detector can sometimes compensate for this effect.

Monochromator

A monochromator, mainly used in a dispersive instrument, is an optical device capable of separating infrared radiation into its constituent wavelengths. The monochromator

normally consists of several components, including mirrors for collimating, focusing, or changing the direction of the radiation beam, and filters for attenuating the radiation and reducing stray radiation or eliminating unwanted grating orders. The most important component is the prism or the diffraction grating. By rotating the prism or grating, different wavelengths pass across a fixed slit, thereby allowing the entire wavelength range to be scanned. In most cases, the grating is preferable to the prism because the prism has several disadvantages, including lower dispersion (resulting in lower resolving power) and the introduction of unwanted reflection off its front and back surfaces.

Interferometer

The interferometer used in a nondispersive instrument is a device that divides the beam of radiation into two paths and recombines the two beams after a path difference has or has not been introduced. The basic concept of the interferometer was introduced by Michelson almost a century ago (Fig. 2). It consists of a stationary mirror, a moving mirror, and a beam splitter. The radiation from the infrared source is divided at the beam splitter; half the beam is passed to a fixed mirror and the other half is reflected to the moving mirror. The two beams are later recombined at the beam splitter and passed through the sample to the detector. For any particular wavelength, the two beams interfere constructively or destructively, depending on the difference between the optical paths of the beams in the two arms of the interferometer. The sample placed in the beam path absorbs radiation of a certain wavelength. The recorded interferogram is the sum

Table 1 Radiation sources for infrared spectrometers

Source	Composition	Operating temperature (°C)	Infrared range	Remarks
Nichrome coil	Nichrome	1100	Mid-IR	Air cooled, reliable, inexpensive, low temperature, less intense than other sources
Globar	Silicon carbide	1300	Mid-IR or Far-IR to 2000 cm^{-1}	Cooled by water, emission can be down to 80 cm^{-1}
Nernst glower	Oxides of zirconium, thorium, and yttrium	1500	Mid-IR $10,000\text{--}500\text{ cm}^{-1}$	Poor emission at high wavenumbers, brittle, preheating required
High-pressure mercury arc	Mercury		Far-IR	Best for range between 200 and 10 cm^{-1}
Tungsten lamp	Tungsten		Near-IR	Best for between $33,000$ and 400 cm^{-1}

of all waves except those absorbed by the sample. By a Fourier transformation of the interferogram, a conventional IR spectrum is obtained.

Detector

The detector converts infrared radiation into an electrical signal. The two main classes of detectors are thermal and quantum detectors. The heating caused by impinging infrared radiation changes some physical properties of the thermal detector itself. In quantum detectors, the quantum nature of infrared radiation changes the detector's electrical properties.

The responsivity (E) or specific detectivity (D^*) and the noise equivalent power NEP (W_n), are often used to measure the sensitivity of a detector. The responsivity depends on the wavelength of the radiation and the temperature of the detector. The NEP, also called minimum detectable power, is the quotient of detector noise (N) divided by voltage responsivity (E). The D^* is the reciprocal of NEP, thus $W_n = N/E$ and $D^* = 1/W_n$. A more sensitive detector has a smaller NEP and larger D^* , which results in less noise and a faster response time.

Thermal Detectors

Thermal detectors absorb infrared radiation and convert it to heat, resulting in a temperature change; a temperature-dependent detector property is then measured. The properties of the detector affected by the infrared radiation, depending upon the type of detector, include

the expansion of a liquid, solid, or gas, electrical resistance, voltage, and electric polarization. Thermal detectors respond to radiation over a wide range of wavelengths. Since the response depends upon a change in temperature, such detectors are usually slow, typically responding in about 0.01–0.1 s. Table 2 summarizes the characteristics of various types of thermal detectors.

Quantum Detectors

Quantum detectors are usually made of semiconductor materials or mixtures. Some commonly used quantum detectors are made of lead sulfide (PbS), lead selenide (PbSe), indium antimony (InSb), or mercury cadmium telluride (MCT, HgTe–CdTe). The absorption of infrared radiation in quantum detectors excites electrons from a non-conducting state into a conducting state, resulting in a change in the current or voltage. Since the excitation of the electrons to a higher energy state is quantized, the detector exhibits a sharp cutoff frequency toward the far-infrared. Cooling is generally required to avoid thermal agitation, which produces internal electrical noise. The temperature to which the detector must be cooled depends on its sensitivity; for example, an MCT detector is usually cooled to liquid nitrogen temperature (77 K), whereas PbS and PbSe can be operated at a temperature just below ambient. Quantum detectors have much higher sensitivity and faster response times than thermal detectors; they thus are most often used in high-performance FTIR spectrometers. The response time for quantum detectors is measured in microseconds rather than in milliseconds. The sensitivity of quantum detectors is strongly dependent upon the composition of the semiconductors.

DISPERSIVE INFRARED SPECTROMETERS

Dispersive IR spectrometers can be either single-beam or double-beam; usually they are double-beam instruments. The use of a double-beam instrument significantly reduces the problem of possible interference from carbon dioxide and water vapor in the atmosphere during analysis. The absorption due to a solvent may also be nearly cancelled by placing an equivalent pathlength solvent cell in the reference beam.

A typical double-beam spectrometer is shown in Fig. 3. Radiation from the source is split into the reference beam and the sample beam. Each beam passes through a comb-shaped attenuator that regulates the beam intensity. The two beams are alternately sent through the slit into the

Fig. 2 Diagram of an interferometer. (Adapted from Ref. 23.)

Table 2 Thermal detectors for infrared spectrometers

Detector	Composition	Physical property affected	Remarks
Thermocouple and thermopile	Bismuth and antimony	Voltage at the junction of the two metals	Simplest and most direct measurement; slow response (30 ms)
Thermistor or thermistor bolometer	Oxides of Mn, Co, and Ni	Resistance changes	Slow response
Golay pneumatic detector	Xenon gas	Gas expansion, combined with the moving of a diaphragm, changes the illumination of a photocell	Extends to far-IR region with proper window; 15 ms response time; sensitive to intense light; microphonic disturbances; diaphragm wears out easily
Pyroelectric detector	Polarized pyroelectric materials ^a at temperatures below its Curie point	Electric polarization produces voltage changes	Low noise and fast response; used for fast-scan FTIR

^aSuch as triglycine sulfate (TGS), deuterated triglycine sulfate (DTGS), LiTaO₃, LiNbO₃.

monochromator by the chopper motor, which typically rotates at a frequency of 11 or 13 Hz. After the radiation has been dispersed into its constituent wavelengths by the monochromator, the beam is passed through the other slit and then onto the detector. The detection in a double-beam spectrometer is based on the “optical null” principle. In the absence of a sample, the two beams reach the detector with equal intensity and the recording pen is at 100% transmittance. When the sample is present, the beams are not of equal intensity. The difference in the intensity is amplified by an amplifier, which controls the pen motor. The attenuator comb in the reference beam is driven by the pen motor to adjust the intensity of the reference beam and make it equal to the sample beam. A pen moves up and down a chart to record the percent transmittance of the sample beam, and thus monitors the extent to which the attenuator must be driven. The scan motor rotates the prism or grating in the monochromator to scan the spectrum, simultaneously moving the chart under the pen. The chart records the percent transmittance versus the wavenumber (or wavelength). An alternative to the comb is to plot the difference in voltage between the reference and sample beams.

NONDISPERSIVE INFRARED SPECTROMETERS

One type of nondispersive spectrometer employs filters to isolate the wavelength desired; the other type uses an

interferometer, i.e., the Fourier transform infrared (FTIR) spectrometer. Infrared analyzers utilizing simple filters to select the desired wavelength range for analysis are very useful in industrial on-line process control for monitoring a gas or liquid stream. This type of IR analyzer has high sensitivity and selectivity. A more sophisticated model (with microprocessor) can perform multicomponent analyses, calibration, and data reduction; it can also generate reports. The instrumental design of infrared analyzers is beyond the scope of this article.

Fourier transform infrared spectrometers can be single- or double-beam. Most commercial FTIR spectrometers are of single-beam design (Fig. 4). Double-beam FTIR spectrometers (Fig. 5) are less common and only a few are commercially available, and are mostly used for research purposes rather than routine tasks. A double-beam instrument is designed to compensate for atmospheric interference. In most modern IR spectrometers the optical components are manufactured in a sealed and desiccated compartment with the goal of reducing water and carbon dioxide interferences. A laser beam generates a reference signal to monitor the sampling rate and the velocity of the moving mirror, resulting in very accurate wavelengths in the spectra.

The FTIR technique has several advantages over the conventional dispersive technique. It provides a higher accuracy in wavenumber values, a better resolution, a better signal-to-noise ratio in a shorter time, and faster response time, making it useful for in-process or on-line monitoring. Dispersion or filtering of the radiation is not required.

Fig. 3 Schematic of a typical double-beam spectrometer.

Data-Handling System

Most modern infrared spectrometers are equipped with a computer or microprocessor. The computer can record and store spectra, plot either absorbance or transmittance, overlay spectra for comparison, subtract one spectrum from another (to determine the difference or to remove the solvent or impurity spectrum from the sample spectrum), smooth and/or correct base lines, perform multiple scans to increase the signal-to-noise ratio and improve sensitivity, plus many other functions. A computer facilitates the Fourier transform process as well as the solving of complex mathematical matrices for multiple-component analyses.

SAMPLE HANDLING

Infrared spectra may be obtained for gases, liquids, or solids. For transmittance infrared spectroscopy, the sampling techniques may involve a solution, a film, a mull,

or a pellet, depending on the type of sample. Reflectance spectroscopy differs from transmittance spectroscopy in that infrared radiation reflected from the surface of a material is studied. With a proper sampling accessory (obtainable from commercial sources), the materials analyzed by reflectance techniques normally require little or no sample preparation. The method is nondestructive, noninvasive, and very useful for analyzing materials that are too thick or have too much absorbance to be analyzed by transmittance spectroscopy.

Transmittance Spectroscopy

Obtaining the spectrum by transmittance spectroscopy normally requires sample cells with “window” materials that must be:

- Transparent in the wavelength area where the spectrum will be measured
- Chemically stable (nonreactive with the sample or the environment)

Fig. 4 Optical diagram of a single-beam FTIR spectrometer. (From Perkin-Elmer Corporation.)

- Easy to shape, grind, and polish to optical quality
- Stiff enough to retain their shape.

The most widely used window materials (Table 3) are alkali halides, particularly sodium chloride and potassium bromide.

Gases and Low-Boiling Liquids

For routine infrared analysis of gaseous samples, the type of cell normally used has a fixed path length of 10 cm. For trace level analysis, such as air monitoring, a cell with a longer path length is necessary to increase the sensitivity. A variable path cell (Fig. 6) can provide path lengths (in steps of 1.5 m) for 20-, 40-, and 120 m cells with the same volume of sample. A normal sample compartment in an infrared spectrometer does not hold a cell 120 m long. The long-path gas cell therefore utilizes a folded-path design in which the entering radiation is reflected back and forth several times before leaving the cell. Changing the angular adjustment of an internal pair of mirrors with a dial located outside the cell can vary the number of passes through the cell. Increasing the sample pressure to 10 atm in a gas cell is another way of improving the sensitivity.

Liquids and Solutions

For the analysis of liquid samples, the concentration and path lengths are selected in such a way that the transmittance lies between 15 and 75%. For neat liquids, a very thin layer (0.001–0.05 mm) is sufficient. For 0.05–10% (w/w) solutions, a cell length between 0.1 and 1 mm is normally used. For solution analysis, a compensating cell containing pure solvent is placed in the reference beam of dispersive instruments (a disadvantage for single beam FT instruments). In general, the solvent selected should not interact strongly with the solute. Several solvents are usually required to cover the entire spectrum. For example, carbon tetrachloride, transparent for the region between 4000 and 1333 cm^{-1} , and carbon disulfide, transparent for the region between 1333 and 650 cm^{-1} , may be used together. Some commonly used solvents are deuterated chloroform, methylene chloride, acetonitrile, and acetone. Information regarding the transparent regions for these solvents can be found in (1). A dilute solution in a nonpolar solvent usually gives the best spectrum.

Three types of sample cells are used in liquid analysis: sealed, demountable, and variable thickness cells (fixed and rotating windows). Fig. 7 shows a circular demountable cell and a circular sealed cell, both designed by Perkin-Elmer. A sample cell with rectangular shaped

Fig. 5 Schematic of a double-beam FTIR spectrometer.

Fig. 6 A variable-path gas cell. (Adapted from Ref. 30.)

windows is also commercially available. The sealed cells are designed for quantitative analysis. The demountable cells are easily cleaned and suitable for routine sample analysis. The path length of a demountable cell can be changed with a suitable spacer. The path length of a variable-path cell in some cases can be varied continuously from 0.025 to 6 mm. This type is useful for determining extinction coefficients in liquid studies and for compensating for solvent absorption in dispersive double-beam spectrometers. Flow-through cells are available for continuous analysis of liquids such as the column effluent when an infrared spectrometer is coupled to a chromatographic system.

Solids

Solids may be examined as a deposited film, a mull, or a pressed disk, or by infrared microscopy.

Films

The deposited-film technique is particularly useful for polymers, resins, and amorphous solids. The samples are dissolved in a reasonably volatile solvent, the solution poured onto a suitable window, and the solvent evaporated by gentle heating or vacuum treatment. One disadvantage of films is that they may cause excessive light-scattering in transmittance spectrometry. This shortcoming can be

Table 3 Properties of infrared-transmitting materials

Material	Transmission range wavenumber (cm ⁻¹)	Refractive index ^{a,b} , at 1000 cm ⁻¹	Solubility g/100 g water at 20°C
Sodium chloride, NaCl	40,000–625	1.49	36.0

overcome by using attenuated total-reflection or internal-reflection sampling techniques.

Mulls

Grinding 2–5 mg of sample in a smooth agate mortar, adding a drop or two of mulling oil to the sample, and continuing the grinding forms a mull of a solid sample. The sample should be ground until the particle size is below $2\ \mu\text{m}$ to avoid excessive radiation scattering. The mull is placed on the mull plates and the film thickness is adjusted so that the transmittance is between 10 and 90%*T*. Commonly used mulling agents are Nujol (a high-boiling mineral oil), hexachlorobutadiene, perfluorokerosene, and chlorofluorocarbon greases (fluorolubes).

Pressed disks

A pressed disk is prepared by grinding a mixture of 0.5–1.0 mg of sample and 100 mg of dry, powdered potassium bromide in a mortar or Wig-l-bug to reduce the

particle size to less than $2\ \mu\text{m}$. The resulting mixture is pressed into a disk under a pressure of 68.9–103.4 MPa (10,000–15,000 psi). A simple-to-operate minipress is also available. Moisture bands near 3448 and $1639\ \text{cm}^{-1}$ appear frequently in spectra obtained by this technique.

REFLECTANCE SPECTROMETRY

A problem that may be encountered when analyzing a solid sample by transmittance spectroscopy is radiation scattering. Employing reflectance spectroscopy can sometimes reduce this problem. With this technique, the infrared spectra of most solid materials are easily obtained with little or no sample preparation. Spectra of a wide range of solid samples can be characterized with this technique, such as coatings on beverage containers and silicon wafers, polymer films, or other intractable samples.

The reflectance technique, however, is less sensitive than the transmittance technique since about 80% of the infrared radiation is lost after being reflected off the sample surface.

Different types of reflectance spectroscopy depend upon the reflecting behavior of the radiation on the solid. Fig. 8 illustrates various categories used to distinguish techniques for reflecting radiation off solids. Specular reflection spectroscopy is used to measure the reflectance spectrum of a smooth, glossy surface. In reflection-absorption spectroscopy, the radiation passes through a thin surface film on a reflective (typically metallic) surface twice. The thickness of the surface film is normally between 0.2 and 20 μm . This technique is often used in studying the coatings on beverage containers and on silicon wafers of semiconductor devices. Diffuse-reflectance spectroscopy is applied to samples with a coarse, grainy texture such as powders, fibers, and rough surfaces.

Attenuated total-reflectance (ATR) spectroscopy is a widely used sampling technique, in which a sample is placed in contact with a reflecting medium (a plate or prism shaped material called an internal reflectance element). A beam of radiation entering the prism is reflected internally if the angle of incidence at the interface between sample and prism is greater than the critical angle (a function of the refractive index of the sample and the prism).

The sample absorbs the radiation during this process and an absorption spectrum characteristic of the sample is thus obtained. The spectrum of a sample acquired by the ATR technique is generally comparable to the transmission spectrum, but band shifts have been observed. The ATR technique has been used for materials that are too thick or absorb too strongly to be analyzed by transmission spectroscopy. Aqueous solutions can be analyzed by the liquid ATR technique, which was previously very difficult, using transmission spectroscopy.

Fig. 8 Main forms of reflective behavior.

Most reflectance spectroscopy is carried out utilizing an accessory that can be easily inserted into and removed from the sampling compartment of a conventional spectrometer. These accessories are designed for each application and usually consist of mirrors or prisms for reflecting or focusing the radiation. Most of the sampling accessories for the FTIR spectrometers and the FTIR microscopes are available commercially.

QUALITATIVE ANALYSIS

Applications of IR spectroscopy to qualitative analysis are mainly for the identification of unknown compounds. For a pure substance, an exact match of the IR spectrum of the compound with that of the reference standard is positive identification. It is important that both spectra are measured under the same conditions. A solid substance might have various crystalline forms. Therefore, the IR spectra of standard and sample in a solid state might not be identical. In such cases, equal portions of the test sample and the standard should be dissolved in equal volumes of a suitable solvent. The solutions are evaporated to dryness in similar containers under identical conditions and the test is repeated on the residues. The compound can also be recrystallized from the same solvent and the determination repeated.

INTERPRETATION OF INFRARED SPECTRA

For an unknown compound without a reference standard, important structural information can be obtained from the IR spectrum. Fig. 9 is a simplified illustration of the correlation between the absorption frequency in cm^{-1} and the functional groups [A more comprehensive description of this type of correlation chart is given in (4).] By observing the presence or absence of certain "group frequencies", related to common functional groups such as $-\text{OH}$, $-\text{NH}_2$, $-\text{CH}_3$, $-\text{C}=\text{O}$, $-\text{CN}$, $-\text{C}-\text{O}-\text{C}$, $-\text{COOH}$, etc., the gross structural features of an unknown compound can be quickly determined.

The IR spectrum in the mid-IR region is divided into the functional-group region, $4000\text{--}1300\text{ cm}^{-1}$ and the fingerprint region, $1300\text{--}400\text{ cm}^{-1}$. To interpret an IR spectrum, the hydrogen-stretching vibrations, which appear between 4000 and 2500 cm^{-1} , are investigated first to determine whether the compound is aromatic or aliphatic. A sharp band at 3300 cm^{-1} suggests the presence of $-\text{C}=\text{C}-\text{H}$, a terminal acetylene moiety, and/or an $-\text{NH}$ group. Aromatic and unsaturated

Fig. 9 Structure and infrared absorption bands correlation chart. Transmission ranges for infrared window materials CsI, KBr, ZnSe, KRS-5, BaF₂, CaF₂, and NaCl are also indicated on the chart. (From Perkin-Elmer Corporation.)

compounds appear at 3100–3000 cm^{-1} and aliphatic compounds appear at 3000–2800 cm^{-1} . Unsaturation may also be suggested by C=C and C≡C stretches between 2500–1540 cm^{-1} . Next, the group frequency is examined to establish the presence or absence of certain functional groups such as —OH, —NH, and C=O. The stretching vibration of carbonyl groups occurs in the 1850–1540 cm^{-1} range. The fingerprint region, 1300–909 cm^{-1} , is characteristic of each molecule and, when examined in reference to the other regions, provides positive identification of certain functional groups. The lack of strong absorption bands in the 909–650 cm^{-1} region usually indicates a nonaromatic structure. The group frequency might vary when the molecular environment changes; thus, the shift in frequency provides further structural information for an unknown substance. Some typical examples are the effects of inter- or intramolecular hydrogen bonding, the dimerization of a carboxylic acid, and ring strain within the molecule.

After the IR spectrum has been interpreted, the structural characteristics of the unknown can be narrowed

down to a few compounds in a specific category. For positive identification of an unknown, information on the physical state, melting or boiling point, solubility, and the history of the compound should be obtained. The flame test should be done, and the NMR and mass spectra should be determined. Once the structure of the unknown has been deduced, the IR spectrum of the unknown can be compared with available IR reference spectra (5, 6). With FTIR spectrometers, a large collection of IR spectra can be stored in the computer's library. When the IR spectrum of the unknown is obtained, the instrument can do a library search and find the spectrum that offers the best match to the unknown.

If the unknown substance is not pure or is mixed with other components, separation of the compound from the matrix may be required. However, in many cases mixtures may be characterized. The compound can be purified by recrystallization, distillation, solvent-partitioning, pH manipulation, or chromatographic separation. Once the appropriate separation procedures have been completed, the purified unknown can undergo the structural characterization steps described above.

QUANTITATIVE ANALYSIS

The amount of infrared radiation absorbed by the sample is proportional to the concentration of the sample and the cell path length. The Beer–Lambert law, shown in Eq. 7, illustrates the mathematical relationship:

$$A = abc = \epsilon b(\text{cmol. wt.})A = \log_{10}(I_0/I) = \log(1/T) \quad (7)$$

The absorbance A is the logarithm (to the base 10) of the reciprocal of the transmittance (T), which in turn is the ratio of the intensity of the transmitted radiation I to the intensity of the incident radiation I_0 . The absorptivity, a , is the quotient of the absorbance (A) divided by the product of concentration c in grams per liter of the substance and the absorption path length b in cm. The more commonly used molar absorptivity ϵ is used when the concentration is in mol/L rather than g/L.

At a constant cell path length, Beer's law shows that the absorbance of radiation through a medium is proportional to the concentration of the solute. Beer's law is strictly valid only for monochromatic radiation. Stray light (i.e., scattered radiation), which reaches the detector without having passed through the desired beam path, molecular interactions such as hydrogen bonding, which varies with the sample concentration, and other instrumental factors such as slit width, all affect molar absorptivity and result in some deviations from Beer's law. For an accurate analysis of the concentration of an unknown sample, it is usually necessary to first create a calibration curve from standard solutions and then determine the absorbance of the sample under identical conditions. The concentration of the unknown is determined from the calibration curve. Diluted solutions (less than 2%) are recommended for this analysis.

If a calibration curve has been established previously and the instrumental conditions have not been changed, the unknown concentration can sometimes be determined by using a single calibration preparation. The concentration of the unknown is calculated by ratioing absorbances and concentrations, according to Eq. 8.

$$\begin{aligned} A_{\text{std}} &= c_{\text{std}} \\ A_{\text{unk}} &= c_{\text{unk}} \end{aligned} \quad (8)$$

In such cases, the calibration curve of the sample should be determined periodically to make sure that the linearity of Beer's law is still valid.

For quantitative analysis of a single component, a strong absorption band that is relatively free of overlapping bands or interference is selected from the IR

spectrum. The intensity of the band is measured either in units of percent transmittance or absorbance.

The intensity of the incident radiation (I_0) and the intensity of the transmitted radiation (I) can be measured by the base-line method illustrated in Fig. 10. In the FTIR spectrometer, the computer is capable of converting the transmittance into absorbance, subtracting the background or the solvent interference from the sample spectrum, generating a calibration curve, and calculating the unknown concentration.

For quantitative analysis of multiple components in a mixture where overlapping of the bands generally occurs, the number of absorption bands chosen should be equal to the number of components to be determined (n components). A series of standard mixtures (at least as many as n) containing a known amount of the substance is prepared. The resulting equations, involving the science of chemometrics, are solved by matrix algebra methods with the help of a computer. The accuracy of this type of quantitative analysis technique decreases with an increasing number of components in the mixture.

APPLICATIONS AND RECENT DEVELOPMENTS

With the continuous improvement of sampling techniques, software, and instrumental designs, more and more sophisticated FTIR spectrometers are now available. *Analytical Chemistry* biannually reviews the most recent developments in many fields of analytical techniques, including infrared spectroscopy, many times on a yearly basis.

Fig. 10 Illustration of a base-line measurement method. (Adapted from Ref. 29.)

Hyphenated Techniques

Hyphenated techniques refer to the combination of one or more analytical techniques for problem solving and fundamental research. Numerous types have been reported in the scientific journals. Frequently the FTIR spectrometer is coupled with chromatographic instruments for the structural characterization of a column eluent. These systems are designed to monitor the eluent or to obtain its spectrum. Much of the development has been focused on the sampling technique and the design of the interface between the chromatographic system and the FTIR spectrometer to improve the performance of the system.

For GC–FTIR, headspace GC–FTIR, or GC–FTIR–MS, a light-pipe gas cell, direct deposition, or a matrix isolation apparatus is usually incorporated. The mobile phase is helium or nitrogen, which does not interfere. In general, the matrix-isolation technique gives a better quality of infrared spectrum and a lower detection limit. Organic material present as low as a picogram can be detected by this technique (7, 8).

For HPLC–FTIR, GPC–FTIR, or SFC–FTIR, the design of the interface is more challenging since the mobile phases used for these chromatographic systems normally have strong infrared absorbencies; thus, it is important to remove the mobile phase prior to measuring the spectrum. For the interface between the two systems flow-cells or mobile-phase elimination techniques may be used. Some recent developments point toward the elimination of mobile-phase techniques (9–11). A microbore column can help to reduce the mobile-phase volume in the system (12, 13).

FTIR Microscopy

Fourier transform infrared microscopy is the primary infrared technique for structural identification of materials at microquantities. The method is nondestructive and noninvasive. When using a proper transmittance sampling technique and a proper detector, the limit of detection can be as low as the picogram level. In the pharmaceutical industry, FTIR microscopy is used to analyze bulk drugs, excipients, and particulate contaminants (14). Recent studies have shown that by coupling FTIR microscopy with GC, HPLC, SFC, or GPC systems, the detection limit of the method is substantially improved (15, 16).

Infrared Analyzers

The combination of the fast-response FTIR spectrometer and proper sampling techniques has made the infrared

analyzer the instrument of choice for the on-line monitoring of a process stream. The IR analyzer is generally compact, rugged, and easy to operate in the field or industrial production. The infrared analyzer equipped with a microprocessor or a computer is capable of identification and quantitative analysis of single or multiple components in the industrial process stream in a short time. FTIR analyzers are widely used for in-process on-line monitoring of manufacturing, waste streams, and environmental air monitoring (17–21).

SUMMARY

Infrared spectroscopy continues to be a rapidly growing analytical technique. Improvements and innovations have been made in sampling techniques and analysis software. A large variety of samples in various forms can be analyzed by IR spectroscopy. This flexibility has made infrared spectroscopy one of the most important tools in today's analytical laboratories, especially for analysis of trace contaminants.

SPECTROSCOPIC METHODS OF ANALYSIS—MASS SPECTROMETRY

Mike S. Lee

Milestone Development Services, Newtown, Pennsylvania, U.S.A.

INTRODUCTION

The dramatically increased expenditures for both in-house and outsourced pharmaceutical research and development (R&D) have led to a greater dependence on technology. New technologies are constantly introduced into drug development to address throughput issues and improve development cycles. The incorporation of new technologies has resulted in fundamental change in the drug development paradigm. Recently, sample generating-based technologies such as high throughput biomolecular screening and automated parallel synthesis have shifted the bottleneck to sample analysis-based technologies.

The current focus on analytical techniques in the pharmaceutical industry emphasizes four primary figures of merit: sensitivity; selectivity; speed; and high throughput. Mass spectrometry (MS) provides each of these key attributes, and therefore, has been benchmarked an effective solution for pharmaceutical analysis in each stage of drug development (1). Perhaps more enabling than the MS-based technology itself is the diverse applications of MS in conjunction with sample preparation, chromatographic separation, and informatics. It is within this context that MS has played an increasingly vital role in the pharmaceutical industry and has become the preferred analytical method for trace-mixture analysis (Fig. 1).

A variety of MS formats are widely accepted and applied in the pharmaceutical industry. The specific MS application is often defined by the sample introduction technique. The pharmaceutical applications highlighted in this article feature two types of sample introduction techniques: dynamic and static. Dynamic sample introduction involves the use of high-performance liquid chromatography (HPLC) on-line with MS. The resulting liquid chromatography/mass spectrometry (LC/MS) format provides unique and enabling capabilities for pharmaceutical analysis. The electrospray ionization (ESI) (2) and atmospheric pressure chemical ionization (APCI) (3) modes are the most widely used. Static sample introduction techniques primarily use matrix-assisted laser desorption/ionization (MALDI) (4).

The advances in MS instrumentation (5) and role of MS within the pharmaceutical industry (1) have been recently

reviewed. This article will focus on MS technologies with regard to specific applications in drug development. The intent of this article is to provide an overview of MS applications and describe the significant integration of this technology into drug development. A detailed and in-depth overview of current MS technologies and applications can be obtained from the recent proceedings of the American Society for Mass Spectrometry Conference on Mass Spectrometry and Allied Topics (www.asms.org) and the Association of Biomolecular Resource Facilities (www.abrf.org).

GENOMICS

Though the contributions of MS have been somewhat limited in the field of genomics, there has been increased participation and interest (6). Certainly, the worldwide recognition received from the Human Genome Project created a sense of urgency toward determining genetic variation.

Genomics refers to the study of genetic data to draw correlation between individual genetic inheritance and medically or biologically important parameters. For example, these parameters may involve a patient's response to a specific drug. Knowledge of the genetic basis of individual drug response may provide understanding of the observed variability in drug response arising as a result of genetically determined differences in drug absorption, disposition, metabolism, or excretion (7). Furthermore, knowledge of genetic variation may be useful during the target selection process when multiple targets are available within a specific disease state. Thus, the pharmaceutical industry has great interest in determining the genetic variation in patient populations.

Due to the existence of sequence variations, or polymorphisms, no two human genomes are identical. Single nucleotide polymorphisms (SNPs) are the most abundant genetic variation with an estimated frequency of 1 SNP per 500 basepairs. Since SNPs are so prevalent in the genome, they can act as markers that are linked with a phenotype to provide a comprehensive measure of interaction with a specific drug. The validation of

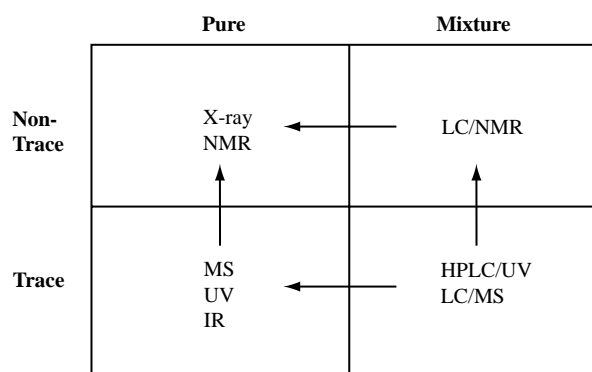

Fig. 1 Structure analysis matrix that illustrates pharmaceutical analysis preferences for four specific sample types: nontrace/pure; nontrace/mixture; trace/pure; and trace/mixture. (Courtesy of Milestone Development Services, Newtown, PA.)

a particular SNP represents an important stage for establishing SNPs as a routine clinical diagnostic marker. The validation of SNPs via MALDI-TOF MS is emerging as a valuable genotyping tool (8, 9). A schematic of a MALDI-TOF MS instrument is shown in Fig. 2.

A recent study performed by Stroh et al. (10) compared the performance of MALDI-TOF MS with restriction fragment length polymorphism (RFLP) and fluorescence polarization (FP). The study involved the analysis of known mutations of the IL-1 β gene. The procedure involved amplification of patient DNA samples using standard PCR techniques followed by a primer extension step where a separate post-PCR primer is hybridized

directly adjacent to the SNP site. The resulting MALDI-TOF MS data provided a direct confirmation of molecular weight for fast analysis of polymorphisms.

Knowledge of the DNA sequence flanking the SNP site allows for the optimum choice of post-PCR primer size, primer location, and dideoxy-nucleotide(s). Thus, the assay can be designed to extract complete information about the SNP regardless of its state. This emerging MS-based approach for SNP genotyping has potential to be highly automated without the requirement for fluorescent tags. Furthermore, "multiplexing" can be attained by selecting post-PCR primers of varying lengths to dedicate predetermined regions of the mass spectrum to specific SNPs.

PROTEOMICS

The study of protein structure, function, quantity, and interactions during maturation and progression of disease is referred to as proteomics. Analytical approaches that use a combination of two-dimensional (2-D) gel electrophoresis for protein separation and MS analysis for protein identification followed by database searches is a widely practiced proteomics strategy (11). The tryptic peptides extracted from gels are analyzed by MALDI-TOF MS and microcolumn or capillary LC tandem mass spectrometry (MS/MS) techniques. Typically, the MALDI-TOF MS techniques are used to quickly identify peptide fragments and confirm the presence of known proteins. Nano-scale

Fig. 2 Schematic of a MALDI-TOF MS instrument. MALDI-TOF samples are prepared with a matrix that contains a small organic molecule capable of absorbing ultraviolet light. A laser is used to desorb ions from the sample plate and the resulting ions are forced into the flight tube by application of the acceleration voltage from extraction grids. All ions leave the source with the same kinetic energy and travel down the flight tube toward an ion reflector. Separation is based on mass with lighter ions traveling faster than heavier ions. The ion reflector is used to correct for small kinetic energy differences between ions of the same mass resulting in improved resolution and mass accuracy. (Courtesy of Applied Biosystems, Framingham, MA.)

Fig. 3 Schematic of a nano-scale capillary ESI interface. This specialized LC/MS interface, operating at flow rates from 20 to 500 nL/min and using 50 to 100 μm ID columns, typically provides low femtomole sensitivity. Fully automated sample handling and preparation procedures (i.e., desalting and preconcentration) combined with specialized devices for high separation and variable nL gradient flow rates provide unique capabilities for high-throughput analysis of proteins. (Courtesy of New Objective, Cambridge, MA.)

capillary LC/MS/MS techniques (using 50–100 μm diameter columns, operating at flow rates of 20–500 nL/min) are used to further interrogate the complex protein mixture at the low femtomole level. These techniques require the use of a specialized ESI source shown in Fig. 3.

The combination of MALDI-TOF MS and capillary LC/MS/MS was recently described for the identification of disease state markers in human urine (12). In this study, urine proteins obtained from emphysema patients were separated on 2-D gels and selected spots were digested with trypsin and analyzed by MALDI-TOF. A database search using Protein Prospector identified a potential biomarker for emphysema as human α -1-antitrypsin (A1AT). The corresponding MALDI spectrum contained nine out of 18 peptides with masses that match the expected tryptic digest fragments for A1AT.

The same tryptic digest protein sample was analyzed by capillary LC/MS/MS using an ion trap mass spectrometer followed by a database search with SEQUEST. Figure 4 illustrates the components of an ion trap mass spectrometer. The highly automated data-dependent MS/MS analysis provided excellent sequence coverage for 11 tryptic peptides related to A1AT in a single LC/MS run. A tryptic peptide that corresponds to the A1AT sequence SVLGQLGITK observed at retention time (r_t) 30.5 min. was observed in the spectrum. The LC/MS data also

provided sequence information on unmatched MALDI peaks.

The need to detect lower concentration of protein and peptide mixtures has resulted in the increased use of hybrid quadrupole/orthogonal TOF (QTOF) MS/MS instruments (13) in conjunction with microcolumn LC. Fig. 5 shows a schematic of a QTOF instrument. This LC/MS approach provides a resolution of ca. 0.1 mass units allowing for the analysis of complex product ion spectra (14, 15). A recent publication by Chalmers and Gaskell highlights the current challenges in proteome analysis with regard to MS instrumentation (16).

NATURAL PRODUCTS DEREPLICATION

Historically, an excellent source of novel lead drug compounds is natural products. Natural product screening activities typically occur during drug discovery and involve the testing of crude extracts obtained from microbial fermentation broths, plants, or marine organisms. When activity above a certain level is detected, active components are isolated and purified for identification. This process is often time-consuming, where the physicochemical characteristics of the active components

Fig. 4 Schematic of an ion trap MS instrument. This device consists of two endcap electrodes (entrance and exit) and a ring electrode. An ion trap MS separates ions based on mass-to-charge ratio (m/z). Once ions are introduced into the ion trap MS, the radiofrequency (rf) amplitude is increased so that ions are sequentially ejected (by increasing mass) and detected. This type of MS provides a routine (i.e., benchtop) and sensitive detector using either GC and LC interfaces. Furthermore, this instrument provides a unique format for multiple stages of MS analysis (MS^n). (Courtesy of Thermo-Finnigan, San Jose, CA.)

are determined, known compounds are identified (dereplication), and the novel compounds are scaled-up for more detailed investigation.

Analysis strategies that use on-line ESI-LC/MS approaches provide an integrated format for natural product dereplication by combining traditional fraction collection, sample preparation, and multi-component analysis into a single step. In this way, crude extracts are screened without extensive purification and chemical analysis. Furthermore, less material is required due to the sensitivity of the technique and chromatographic resolution is retained.

The key to natural products analysis using this approach is dependable molecular weight determination. This information is used with existing natural product databases that contain information on the bioactive compounds, the physical descriptions of the microorganisms from which they come, their spectrum of activity, the method of extraction and isolation, and physical data (i.e., molecular weight, UV absorption maxima). Molecular weight is the most critical information for initial searches because of its link to structural specificity. This information is used to make pivotal decisions on whether or not to proceed to more time-consuming isolation steps based on novelty of the compound. In recently reported studies (17, 18), LC/MS is used to increase sensitivity and accelerate analysis. These features serve to significantly reduce labor. A recent review described LC/MS-based approaches for

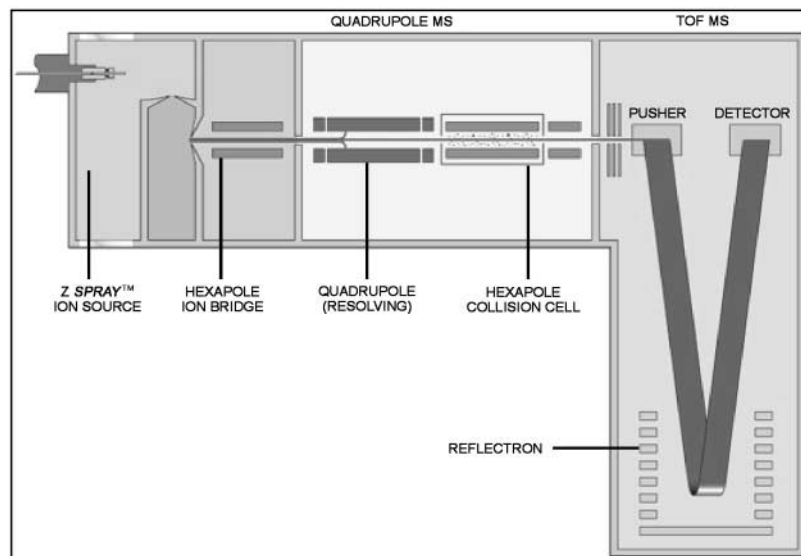

Fig. 5 Schematic of a QTOF MS instrument. Ions formed in the source region are introduced into a quadrupole mass filter (see Fig. 7) that separates ions based on mass-to-charge ratio (m/z). Selected ions are then transferred into the TOF MS for detailed analysis (i.e., high resolution capabilities). (Courtesy of Micromass, Manchester, UK.)

the characterization of natural product mixtures in conjunction with high-throughput screening (19).

The instrumental configuration of the LC/MS system developed by Ackermann et al. (17) features an HPLC, UV detector, fraction collector, ESI-tandem quadrupole (MS/MS), and MALDI-TOF MS. Filtered fermentation broths were extracted with butanol or ethyl acetate, and eluted on a gradient C18 reversed-phase HPLC separation. The eluent was split 1:10 between a tandem quadrupole MS/MS instrument (scanning 250–2000 amu/3 sec in the full scan mode) and a single wavelength UV detector (254 or 230 nm). One-min fractions were collected after the UV detector. Of these fractions, 20–50 μ L is used for MALDI-TOF analysis, and the remainder is concentrated for microbiological testing. The LC/UV chromatogram was compared to the bioactivity assay histogram to highlight the peaks that contain activity. The molecular weights of the active peaks were obtained for novelty assessment of the compounds.

Similar approaches that use on-line LC/MS and LC/MS/MS techniques have been recently described for natural products dereplication (20, 21). Approximately 1,000 natural product extracts can be screened annually for *in vivo* and *in vitro* activity using LC/MS-based systems. A standard approach for dereplication involves a comparison of retention time, full scan mass spectra (i.e., molecular weight information), and MS/MS spectra with those from known biologically active standards. Thus, previously identified components are rapidly eliminated and do not require time-consuming structure elucidation studies. The savings of effort allow researchers to focus efforts on novel chemistries. Samples of novel compounds can then be infused into an ion trap mass spectrometer, and a multiple stage mass analysis (MS^n) fragmentation map is generated.

COMBINATORIAL CHEMISTRY

Recent reviews (22, 25) describe MS-based methods ranging from the analysis of complex molecular libraries (26) to open-access formats for drug discovery and development (27). High throughput criteria were central to each application.

An important development in the quest for high throughput combinatorial library analysis was the multiple ESI interface described by Wang et al. (28). This novel ESI interface enabled effluent flow streams from an array of four HPLC columns to be sampled independently and sequentially using a quadrupole MS instrument. The interface featured a stepping motor and rotating plate

assembly. The effluent flow from the HPLC columns was connected to a parallel arrangement of electrospray needles co-axial to the mass spectrometer entrance aperture. The individual spray tips were positioned 90° relative to one another in a circular array. Each spray position was sampled multiple times per second by precise control of the stepping motor assembly.

The parallel sample analysis format using a multiplexed LC/MS interface with an orthogonal time-of-flight (TOF) MS was described by de Biasi et al. (29). This approach illustrated the high-throughput capabilities of a multiplexed ESI interface in combination with an MS format that accommodates fast chromatography methodologies. The system featured a four-way multiplexed electrospray interface attached directly with the existing source of the TOF-MS instrument. A rotating aperture driven by a variable speed stepper motor permitted the sampling of the spray from each electrospray probe tip. The data files were synchronized with the corresponding spray.

As the preparation of large libraries for lead discovery became routine, the burden placed on analysis techniques focused mainly on throughput and quality (30). However, biological assay requirements typically required pure compounds. Thus, the focus shifted toward the use of automated high throughput purification methods applied to libraries of discrete compounds (31). Reverse-phase analytical and preparative HPLC formats in conjunction with MS techniques have been critical for the high throughput purification approaches for parallel synthesis libraries. A variety of approaches that featured the use of gradient methods, short columns, and high flow rates have been described (32). Highly automated LC/MS approaches for purification at the multimilligram level were described for a quadrupole system by Zeng et al. (33). These methods featured the use of short columns that were operated at ultra high flow rates. Preparative columns were operated at flow rates in excess of 70 ml/min to match the linear velocity of the short analytical columns (4.0 ml/min). Analytical LC/MS analyses of compound libraries were achieved in 5 min for chromatographically, well-behaved compounds. Slightly longer preparative LC/MS analysis times (8–10 min/sample) were required for compounds that exhibited poor chromatographic peak shapes and/or for compound mixtures the required higher resolution separations. The fraction collection process is initiated in real-time once the reconstructed ion current is observed for a specific m/z value that corresponds to the compound of interest. This design permitted the collection of one sample per fraction. Thus, the need for very large fraction collector beds and postpurification screening and pooling was eliminated. Unattended and automated

operation of this system led to the purification of overcompounds (mg quantities) per day.

BIOAFFINITY SCREENING

With the integration of highly automated parallel synthesis techniques into drug discovery programs, hundreds of thousands of compounds are now screened against a particular biological target. Once activity is determined for a mixture, the identification of the active component(s) is necessary. A recent study described the use of bioaffinity selection LC/MS methods for the identification of active mixture component(s) (34). This approach features an integrated bioaffinity-based LC/MS screening method to separate and identify compounds from mixtures.

A mixture of compounds is incubated with the target protein and the components bound to the protein are selected by using a size exclusion chromatography (SEC) "spin column." In this experiment, the unbound compounds are retained on the column. The bound components are eluted and identified with LC/MS. Increased specificity is obtained by dissociating the bound compounds and performing a second equilibration incubation with the protein. This procedure preferentially selects for the compounds with higher affinity, and results in an enhancement of the quantitative LC/MS response. Iterative stages of incubation, size-exclusion, and LC/MS allow the tighter binding components to be enriched relative to weaker binding components.

In this study, the peroxisome proliferator-activated receptor (PPAR γ), which is a target for anti-diabetic drugs (construct molecular weight of 32,537 Da), is incubated with 10 ligands that range in molecular weight from 283 to 587 units. A spin column of 6000 Da cutoff is used for SEC purposes. The retained mixture of components is analyzed by fast perfusive chromatography (35, 36), using a standard full-scan LC/MS strategy. This analysis procedure allows for the identification and quantitation of the protein and the ligands, compared to their responses prior to incubation. The ligand-protein complex that dissociated under the reversed-phase chromatographic conditions is selectively detected.

This analysis scheme provided a quick measurement of binding affinity, and serves as a screening tool during drug candidate selection. Spreadsheets were constructed and used to calculate the binding affinity of the components. In the example described above, two incubation cycles followed by the SEC separation provided an enhancement of strong binders to weak binders. This LC/MS-based method provides a unique approach to obtain information

in situations when lower concentrations of tighter binding ligands are present in the same mixture with higher concentrations of weaker binding ligands. Furthermore, this method is more efficient than synthetic deconvolution procedures and does not require the use of radioligands.

Combinatorial chemistry initiatives have created a tremendous challenge for activities that deal with the screening of these mixtures for activity against a specified target (37). MS-based approaches that use affinity selection (38), encoding methodologies (39–41), pulsed ultrafiltration (42), and anti-aggregatory approaches (43) have been described.

The use of MS formats that provide accurate mass capabilities have been recently illustrated for screening combinatorial libraries (44–47). The unambiguous confirmation/identification of combinatorial library components from small quantities of material have been illustrated using a hybrid quadrupole/orthogonal TOF (QTOF) (44, 45) and Fourier transform ion cyclotron resonance (FTICR) (47) mass spectrometry. A schematic of a FTICR-MS system is shown in Fig. 6. Accurate isotope patterns or "isotopic signature" and unique mass differences between isobaric compounds can be obtained using these two MS formats.

OPEN-ACCESS SYSTEMS

Chemists now routinely use open-access MS systems in the same way that they previously used thin-layer chromatography (TLC) to monitor reaction mixtures for the desired product and to optimize reaction conditions. In practice, medicinal chemists require only molecular weight data, and are comfortable with a variety of MS ionization methods to obtain this information. However, confidence in the actual method and procedure is a requisite. Today, molecular mass measurement has quickly become a preferred means of structure confirmation over NMR and IR during the early stages of synthetic chemistry activities (i.e., drug discovery), where sample quantities are limited.

In the open-access LC/MS procedure described by Pullen et al. (48), the samples are directly introduced from solution for ease of automation and sample preparation. Chemists prepare samples in solvent to a suggested concentration range, then log the samples into the system. The sample log-in is done at any time during the continuous automated queue. Autosampler vials are used to hold the samples, and autosamplers are used to directly deliver samples in solution to the mass spectrometer. The system uses a standard method to analyze the samples in

Fig. 6 Schematic of a FTICR MS instrument. This type of MS consists of an ion cyclotron resonance (ICR) analyzer cell that is situated in the homogeneous region of a large magnet. The ions introduced into the ICR analyzer are constrained (trapped) by the magnetic field to move in circular orbits with a specific frequency that corresponds to a specific mass-to-charge ratio (m/z). Mass analysis occurs when radiofrequency (rf) potential is applied (pulsed) to the ICR analyzer so that all ions are accelerated to a larger orbit radius. After the pulse is turned off, the transient image current is acquired and a Fourier transform separates the individual cyclotron frequencies. Repeating this pulsing process to accumulate several transients is used to improve the signal-to-noise ratio. (Courtesy of Bruker Daltonics, Billerica, MA.)

queue, average spectra according to a preset scheme, and print out a spectrum for the chemist. Fail-safe procedures for untrained users and instrument self-maintenance at start-up and shutdown were also developed.

Taylor et al. (49) further demonstrated the value of open-access LC/MS systems for generating a widened scope of pharmaceutical analysis applications, including: 1) characterization of synthetic intermediates and target compounds; 2) reaction monitoring; 3) reaction optimization; 4) analysis of preparative HPLC fractions; and 5) analysis of TLC plate spots. The availability of these methods led to the increased use of LC/MS for structural analysis. The short analysis time and reliable structure

confirmation resulted in the use of LC/MS as a first choice for structure characterization for synthetic chemistry applications.

Open-access LC/MS formats have spawned new dimensions in access and data management. The use of a direct exposure probe (DEP) for automated sample introduction has been developed for quick (ca. 3 min) molecular weight determination of new lead compounds and quantitative analysis (50). Figure 7 illustrates an automated direct probe system for molecular weight determination. Versatile software packages for data manipulation and processing has been a popular approach for integrating analysis and information (51–53). These software programs are

efficiently implemented with stand-alone computers and servers that are networked with open-access mass spectrometer data systems. In this configuration, the data are generated, visualized, processed, and automatically reported for the chemist. The program compares a template of predicted molecular ions with the actual ions generated by ESI and APCI for the quick analysis of synthetic products, intermediates, reactants, reagents, and contaminants. A list of observed ions along with known artifact ions is generated and used to provide a measure of the quality-of-fit to the predicted product(s).

Open-access MS systems provide an effective means for maintaining the high-throughput characterization of synthetic compounds. These systems offer an efficient laboratory- to bench-scale integration of sample generation and analysis activities. Advances in analytical instrumentation and electronic communication have also

played a major role in the emergence and acceptance of MS as a front-line tool for structure characterization.

IN VIVO DRUG SCREENING

The application of APCI-LC/MS techniques for the rapid determination of protein binding and pharmacokinetics in drug discovery were recently described by Allen et al. using a single quadrupole instrument (54). A “cocktail” approach consisted of four experimental compounds and a control compound dosed orally at 1 mg/kg with plasma samples obtained at 0.5, 1, 2, 4, and 8 h post dose. To insure reproducibility, the control compound was tested with each cocktail. This approach generated timely systemic exposure (AUC and Cmax)

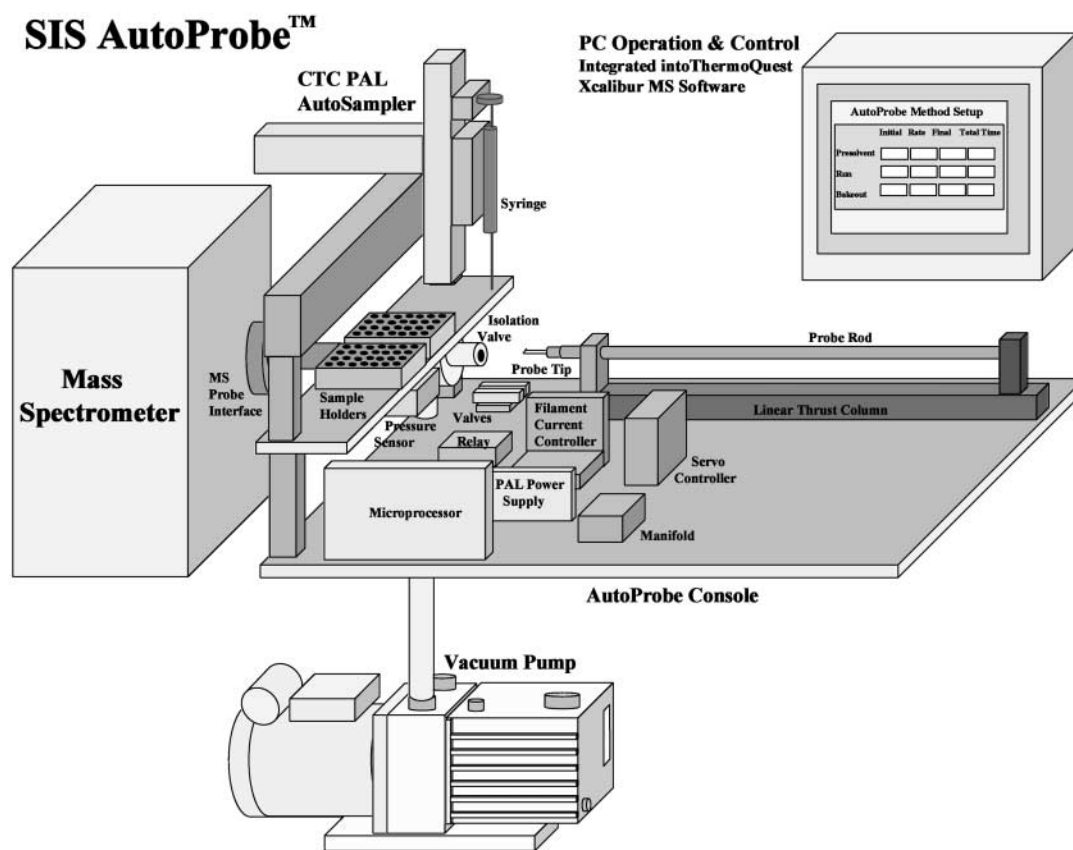

Fig. 7 Schematic of an automated direct probe system for molecular weight determination that features an ion trap MS. Samples are dissolved in a suitable solvent and injected via an automated syringe system onto the DEP wire. The probe is injected into the MS via an automated isolation valve system and the temperature is ramped to the programmed temperature. After sample analysis the probe is removed from the source and heated to a high temperature to clean the DEP wire in preparation for the next sample. This type of integrated, open-access MS-based application provides routine, unattended support for medicinal chemistry needs such as reaction monitoring and the optimization of reaction conditions. (Courtesy of Scientific Instrument Services, Ringoes, NJ.)

data on 44 test compounds in three work days, using two laboratory scientists.

The use of LC tandem quadrupole MS/MS-based screening approaches for quantitative bioanalytical measurements allow a large, chemically diverse, range of potential drug candidates to be analyzed quickly and confidently. A schematic of a tandem quadrupole MS/MS instrument is shown in Fig. 8. The development of unique LC/MS-based systems for *in vivo* pharmacokinetic screening reduces the analysis to a manageable number of samples, and results in a cost-effective approach to evaluate new lead compounds. Approaches to this type of methodology will likely vary, according to the behavior of the molecules of interest, standard operating procedures (SOPs), performance capabilities of the mass spectrometer, and integration of automated sample preparation, and data analysis procedures. Success will likely be dependent on the above parameters, as well as on the degree of tolerance to which the specific screen is set.

The simultaneous pharmacokinetic assessment of multiple drug candidates in one animal has been termed “n-in-one” or “cassette dosing.” As discussed for the previous example, this parallel approach results in an increased productivity for bioanalysis during drug discovery. Beaudry et al. (55) recently investigated the extension of this methodology to study larger numbers of compounds in each mixture, and to integrate sample preparation with the LC/MS/MS system for increased efficiency.

The number of analytes studied in parallel was extended to 63 plus an internal standard. The increased

number of analytes was made possible due to improvements to the collision region of the MS/MS system that provide increased sensitivity and reduced “memory effects.” In addition, robotic systems for sample handling and on-line (solid phase extraction) SPE of plasma samples were integrated with the LC/MS/MS system. An isocratic reversed-phase HPLC method provided a cycle time of 4.5 min per sample. The on-line sample preparation and short analysis resulted in an increased sample throughput that required less time from the scientist. The method produced good performance, in terms of extraction efficiency, linearity, and limit of detection (LOD), and has the capability of analyzing 320–960 samples per day. The strategic emphasis of this approach is on providing high throughput LC/MS methods for evaluating large numbers of drug candidates during drug discovery to eliminate poor pharmacokinetic performers.

METABOLIC STABILITY SCREENING

The use of fast gradient elution LC/MS techniques on a single quadrupole instrument was described for high throughput metabolic stability screening (56). The method uses as HPLC column-switching apparatus to desalt and analyze lead candidates incubated with human liver microsomes. Substrates were selected whose *in vivo* clearance is controlled predominantly by phase I oxidative metabolism as opposed to phase II metabolism or renal

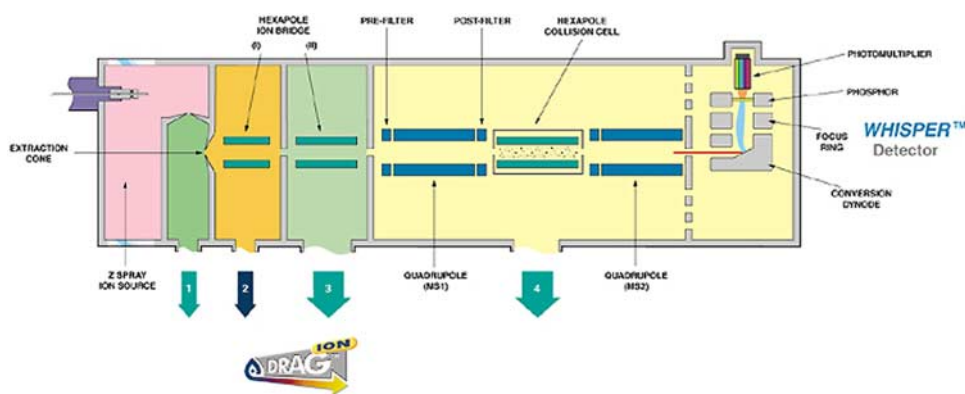

Fig. 8 Schematic of a tandem quadrupole MS/MS instrument. A tandem quadrupole MS/MS instrument consists of two quadrupole MS filters, MS1 and MS2, separated by a collision cell. Each quadrupole MS filter consists of four cylindrical or hyperbolic shaped rods. A unique combination of direct current (dc) potential and radiofrequency (rf) potential is applied to each pair of rods (one pair 180° out of phase with the other). A mass spectrum results by varying the voltages at a constant rf/dc ratio. A variety of scan modes (e.g., full scan, product ion, precursor ion, neutral loss) provide unique capabilities for quantitative and qualitative structure analysis. (Courtesy of Micromass, Manchester, UK.)

clearance. In this way, the resulting data could be resolved into four categories of metabolic stability: high ($\geq 60\%$); moderate ($\geq 30\text{--}59\%$); low ($\geq 10\text{--}29\%$); and very low ($< 10\%$).

The rapid structure identification of metabolites is a powerful complement to previously described quantitative approaches. The utility of an automated metabolite identification approach, using LC/MS/MS with an ion trap mass spectrometer has been demonstrated (57). In this study, MS^n analysis is automated to provide maximum structural information in combination with predictive strategies for biotransformation. Automated data-dependent scan functions are used to generate full scan, MS/MS, and MS^n mass spectra of metabolites within a single chromatographic analysis. This feature is unique and avoids the multiple (2–4) injections that are necessary with other MS/MS configurations (e.g., tandem quadrupole). Along with the significant savings in time, detailed structure information is generated, which enables a comprehensive analysis of substructure relationship to be constructed for each metabolite. These automated studies provide unique advantages during drug discovery, and provide an early perspective on the metabolically labile sites, or “soft spots” of a drug candidate. This knowledge is useful during lead optimization activities, and can lead to the initiation of proactive research efforts that deal with metabolism-guided structural modification and toxicity.

METABOLITE PROFILING AND IDENTIFICATION

The application of LC/MS-based techniques for the structure identification of drug metabolites has played a significant role in drug development. The early identification of drug metabolites provides valuable insights into the pathways of metabolism and biotransformation. Once metabolites are identified/confirmed, metabolism-guided structural modification during the drug discovery stage is initiated to facilitate the selection of drug candidates for subsequent development.

The identification of metabolite structures with LC/MS and LC/MS/MS techniques using quadrupole-based MS instruments are an effective approach due to their ability to analyze trace mixtures from complex samples of urine, bile, and plasma. The key to structure identification approaches is based on the fact that metabolites generally retain most of the core structure of the parent drug (58, 59). Therefore, the parent drug and its corresponding metabolites would be expected to undergo similar fragmentation and to produce mass spectra that indicate major substructures.

Kerns et al. demonstrated the application of LC/MS and LC/MS/MS standard method approaches in preclinical development for the metabolite identification of buspirone, a widely used anxiolytic drug (60). The success of this method relies on the performance of the LC/MS interface and the ability to generate abundant ions that correspond to the molecular weight of the drug and drug metabolites. The production of abundant molecular ions is an ideal situation for molecular weight confirmation because virtually all the ion current is consolidated into an adduct of the molecular ion (i.e., $[M + H]^+$, $[M + NH_3]^+$).

Full-scan mass spectra generally contain an abundant $[M + H]^+$ ion signal with little detectable fragmentation. Product-ion spectra are obtained to reveal product ions and neutral losses that are associated with diagnostic substructures of the buspirone molecule. To assist with the MS/MS structure identification, the gross substructure of buspirone is categorized into *profile groups* (61). Profile groups directly correlate specific product ions and neutral losses with the presence, absence, substitution, and molecular connectivity (62) of specific buspirone substructures and their modifications. The profile groups of buspirone are identified with abbreviations that correspond to the three specific substructures: azaspirone decane dione (A), butyl piperazine (B), and pyrimidine (P). Substituted substructures are designated with a subscript (s), and a dash (–) denotes substructure connectivity. Thus, the buspirone molecule is represented by A–B–P. The A_s –B–P designation refers to metabolite structures that contain the azaspirone decane dione, butyl piperazine, and pyrimidine substructures with substitution on the azaspirone decane dione substructure. The profile group categorization within a corresponding database allows the rapid visual recognition of primary substructures affected by metabolism.

Metabolite structure databases can be easily constructed and contain information on the structure, molecular weight, UV characteristics, RRT, and product ions of metabolites obtained from rat bile, urine, and liver S9 samples. Using this format, Kerns et al. reported the predominant buspirone metabolite profile groups as A_s –B–P, A–B–P_s, and A_s –B–P_s. These profile groups indicate azaspirone decane dione and pyrimidine as metabolically active sites of attack and the presence of multiple substitution sites on each of these substructures.

IMPURITY PROFILING AND IDENTIFICATION

Synthetic impurities are of particular concern during process research and safety evaluation activities. Often,

impurities are the result of synthetic by-products or starting materials of the scale-up process. Impurities provide a comprehensive indicator of the chemical process and are diagnostic of overall quality. Process chemists use this information to guide process optimization. Knowledge of the identity and relative amount of impurities is used to diagnose process reactions so that changes in reagents and reaction conditions leads to better yields and higher quality material.

With an increasing number of novel lead candidates that enter into preclinical development, considerable resources are needed to identify impurities. LC/MS-based approaches provide integrated sample clean-up and structure analysis procedures for the rapid analysis of impurities. This advantage was demonstrated during the preclinical development of TAXOL[®] (18). LC/MS played an important role for the identification of impurities contained in extracts and process intermediates from *Taxus brevifolia* and *T. baccata* biomass. Because drugs derived from natural sources often have a very diverse set of structural analogs, it is important to determine which analogs are carried through the purification process and ultimately appear as impurities. This task presents a unique challenge during the early stages of drug development due to the highly complex nature of the samples.

Kerns and coworkers described a structure identification strategy that incorporates LC/MS and LC/MS/MS techniques using quadrupole-based instruments for rapid, sensitive, and high-throughput impurity analysis (18). This approach integrates traditional steps of sample preparation, separation, analysis, and data management into a single instrumental method. The resulting multidimensional data include retention time, molecular weight, UV, and substructure information. A structure database is developed for each candidate and is used to rapidly identify the same impurities in new samples. Structures are proposed based on using the drug candidate as a structural template and, with the use of a standard method approach, consistency for comparison of results throughout the preclinical development process is ensured.

Nearly all of the impurities contained the characteristic paclitaxel core substructure as indicated by the characteristic product ion at m/z 509 with variations due to modifications. Many of these taxanes contained a side-chain similar to paclitaxel, with variations occurring on the terminal amide of the side chain. The product ions that differed from the characteristic side-chain ions of paclitaxel (m/z 286) by values indicative of specific substructures were used to identify these terminal amide variations. A comparison with the paclitaxel substructural template indicated structural differences beyond the position of the amide group in the side-chain substructure.

When a new impurity was encountered during chemical process research, retention time and molecular weight information were compared to the database for rapid identification. This approach is similar to the procedure described for natural product dereplication. If the compound is not contained in the structure database, then the corresponding LC/MS/MS analysis is performed to obtain substructural detail and the proposal of a new structure.

A standard reversed-phase HPLC method was used for all the samples that are associated with a drug candidate to reduce time-consuming method development/method refinement procedures. Standard reversed-phase methods typically involve a 20–30 min cycle time and provide information for a wide range of compounds. The incorporation of a standard method strategy allows the use of autosampling procedures and standard system software for data analysis.

During the development of TAXOL[®], 90 taxane impurities were rapidly identified and added to the structure database. This MS/MS information was routinely obtained for impurities down to the 100 ng level (injected), and required approximately 2–3 h for the analysis of each sample. The compounds are structurally categorized with profile group terminology. The LC/MS-based methods were significantly faster than the previously used analytical methods based on scale-up, isolation, fractionation, and individual structural analysis. Software tools capable of sample tracking, interpretation, and data storage facilitate the structure profiling of impurities, degradants, and metabolites (63). Key pharmaceutical analysis elements that deal with sample preparation, real-time analysis decisions, databasing, distribution/visualization of results (Fig. 9) and prediction of fragmentation are now highly integrated.

DEGRADANT PROFILING AND IDENTIFICATION

During the course of drug development, the bulk drug and drug formulation are studied under a variety of stress conditions such as temperature, humidity, acidity, basicity, oxidization, and light. Qin et al. described the utilization of stressing conditions that may cause degradation (64). The resulting samples may be used to validate analytical monitoring methods and to serve as predictive tools for future formulation and packaging studies.

A traditional approach to study degradant formation involves similar time-consuming scale-up and preparation steps as described for metabolite and impurity analysis. Similarly, this area of pharmaceutical analysis

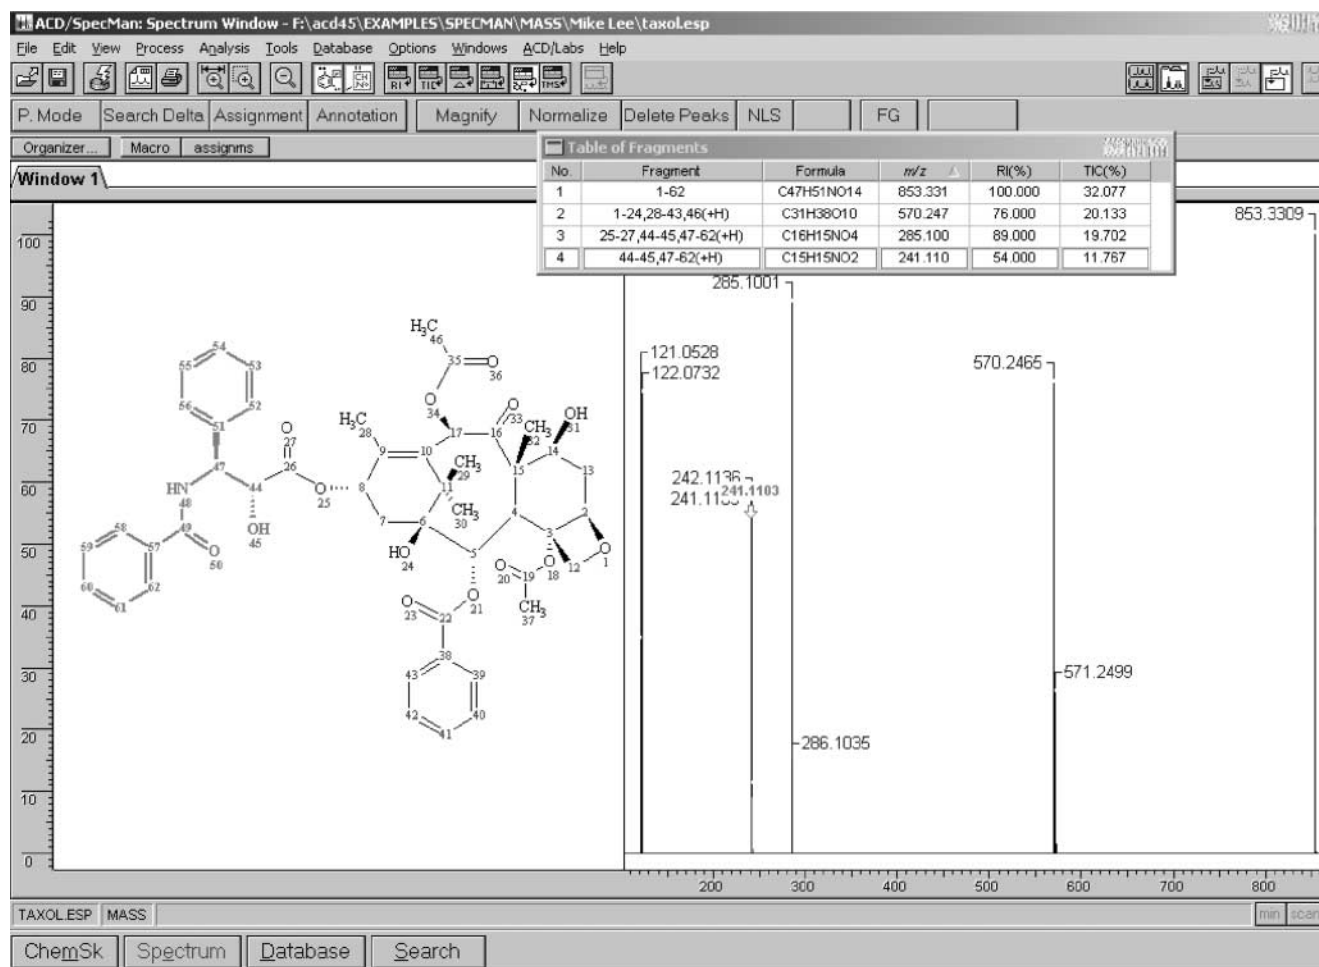

Fig. 9 Visualization of molecular fragments using a “lasso tool” application. The lasso tool is used to identify a particular fragment and, if a signal corresponding to its mass is present in the spectrum, the fragment is highlighted and the corresponding assignment is added to an assignment table. (Courtesy of Advanced Chemistry Development, Toronto, Ontario, Canada.)

has experienced the issues associated with faster drug development cycles. Rourick and coworkers recently described proactive approaches to obtain degradant information with quadrupole LC/MS methods during the preclinical development stage (65). The corresponding structural information provides insight for decisions on which leads to further develop for clinical testing. The early structural information on degradants of a drug candidate offers a unique capability for synthetic modification to minimize degradation. Structural information can also facilitate planning of preclinical drug development in process research, formulation development, and safety assessment.

The strategy for impurity and degradant identification described by Rourick et al. subjects lead candidates to various development conditions followed by LC/MS and

LC/MS/MS analysis protocols. A structure database is constructed from the corresponding results and is used to reveal unstable regions within the drug structure as well as to ascertain which candidate or homologous series of drug candidates may be the most favorable for further development. High capacity and throughput speed are necessary so that many lead candidates may be evaluated. Applicability of the method to a wide range of compound classes is desirable. Once the drug candidate enters clinical development and manufacturing, the structure database is useful for the rapid identification of impurities and degradants in samples generated during these stages of development.

The method exposes drug candidates to forced degradation conditions, (e.g., acid, base, heat, and moisture) as a *predictive profile*. The coordinated use of LC/MS and

LC/MS/MS provide structure identification for speed, sensitivity, and high throughput. Standard methods, useful for 80% of the compounds, are applied. Various types of structural data are obtained for elucidation purposes (e.g., retention time, molecular weight, MS/MS), and unknown compounds are elucidated with the candidate drug as a structural template. The LC/MS analysis provides retention time and molecular weight data, whereas LC/MS/MS provides substructural detail for structure identification. Drug candidates are incubated under drug processing, storage, and physiological conditions that were expected to occur throughout drug lifetime.

Using this approach, 10 degradants of cefadroxil, an orally effective semisynthetic cephalosporin antibiotic, were elucidated in a 2-day study. The use of standard LC/MS methods provided consistency from sample to sample throughout the development process, and allowed for the construction and use of a structural database for the rapid identification of impurities and degradants during development. The reversed-phase HPLC conditions provided a general measure of the polarity of each compound, useful for interpretation of substructural differences between related compounds. Due to the mass-resolving capability of the mass spectrometer, chromatographic resolution of co-eluting or unresolved components was not required. Abundant protonated molecule ions, $[M + H]^+$, provided reliable molecular weight information, and product-ion spectra generated valuable substructure information for each degradant. The product-ion spectrum of cefadroxil was used as a template for interpretation; specific product ions and neutral losses were compared to the spectra obtained from the unknown degradants. Product ions common to each spectrum provided evidence of substructures unchanged by the degradation conditions and differences were indicative of structural variations.

QUANTITATIVE BIOANALYSIS—SELECTED ION MONITORING

The quantitative analysis of targeted components in physiological fluids is a major requirement in clinical development. In 1991, Fouda et al. (66) pioneered the use of APCI-LC/MS on a single quadrupole instrument for the quantitative determination of the renin inhibitor, CP-80,794, in human serum. Because the pharmacological action is below 200 pg/ml, a quantitative assay in the low pg/ml range was required to monitor the drug's pharmacokinetic and pharmacodynamic properties. Also,

the structure of the CP-80,794 molecule lacked a significant chromophore for UV detection with conventional HPLC methods. Furthermore, the low volatility and thermal instability precluded analyses with GC/MS methods.

Quantitative LC/MS assays in clinical development generally involve four intensive steps: sample preparation; assay calibration; sample analysis; and data management. In the method developed by Fouda and coworkers, human serum samples were prepared with a liquid-liquid extraction procedure. Assay calibration involved the use of human serum samples fortified with CP-80,794 at 11 concentrations (6 replicates per concentration) ranging from 0.05 to 10 ng/ml. The LC/MS analysis involved the use of the SIM mode to monitor the molecular ions $[M-H]^-$ that correspond to the drug (m/z 619) and internal standard (m/z 633). In this particular LC/MS application, the negative ion mode was highly sensitive for this class of compound. Samples were loaded onto an HPLC auto-sampler and 80 μ L aliquots are injected onto the column at 4-min intervals. The elution times of the drug and internal standard were 3.1 and 3.4 min, respectively.

At the time, this application provided a powerful benchmark for the use of quadrupole LC/MS-based methods in the pharmaceutical industry and paved the way for the tremendous growth of MS-based applications in support of clinical development. This particular assay successfully supported several clinical studies with sensitive and reliable results. This performance was benchmarked on more than 4000 clinical samples, and led to a widened scope of MS application for quantitative bioanalysis (67–71).

QUANTITATIVE BIOANALYSIS—SELECTED REACTION MONITORING

The use of selected reaction monitoring (SRM) methods for quantitative bioanalysis represents increased dimensions of mass spectrometry analysis. A SRM method that features a tandem quadrupole MS/MS instrument for the quantitative analysis of an antipsychotic agent, clozapine, in human plasma was recently described by Dear et al. (72). Preclinical development studies of clozapine in rats and dogs used HPLC with fluorescence detection (FLD). With this method, a better limit of quantitation (LOQ) of 1 ng/ml was obtained. As the compound moved into the clinical stages of development, a more sensitive method of analysis was required to obtain rapid metabolic information in support of drug safety evaluation studies. As a result, a standard LC/MS/MS method was developed for

the quantitative analysis of clozapine (I) and four metabolites (II-V) in human plasma.

The LC/MS/MS strategy deployed is similar to previously described approaches for protein, natural products, metabolite, and impurity identification. An ionization technique that generates abundant molecular ion species with very little fragmentation is desirable. The product-ion spectrum is obtained to generate the substructural template of the molecule. Abundant and structurally unique transitions (molecular ion \rightarrow product ion) are identified from the spectrum, and are used in the corresponding SRM experiment for quantitation. The SRM experiment provides a high degree of selectivity and better LOD than full-scan or SIM experiments for the analysis of complex mixtures (73, 74). The selectivity of MS/MS reduces the requirements for complete chromatographic resolution of each component. Therefore, LC/MS/MS experiments for quantitation typically emphasize short analytical run times to provide high sample throughput.

The inter- and intra-assay precision (% C.V.) of this method were reported to be less than 8% across the range of the limits of quantification (0.05–10 ng/ml). The accuracy (% bias) for all spiked control concentrations did not exceed $\pm 4\%$. Same-day turnaround of results for over 100 samples was possible and was used to support an acute dose tolerance and pharmacokinetic study that involved the analysis of 1600 samples.

PEPTIDE MAPPING IN QUALITY CONTROL

Quality control involves a carefully designed series of analysis and protocols. The purpose of this activity during the manufacturing stage of drug development is to ensure the production of safe, high quality drug products. These measures are helpful for the producers of the product as well as the regulators (i.e., FDA). In this way, adherence to protocols and procedure are carefully monitored on a routine basis. When any uncertainty in the manufacturing process occurs, procedures are referenced and data are analyzed to determine the specific stage of manufacturing to begin examining. Thus, the responsibility of drug manufacturers and regulating agencies are to determine *when* and *how* a process went awry. The ability to do so in an efficient, straightforward manner is helpful to both parties, and ultimately, the consumer. Thus, the ability to provide this information is highly dependent on the manufacturer's ability to control the process.

The use of LC/MS in a manufacturing quality control environment for biologicals was reported by Chang et al. (75). Their approach involved three steps.

First, the expected cleavage sites (in this case, trypsin) within the amino acid sequence of the protein somidobove are indicated. This "tryptic map" serves as a template for the expected peptide fragments. Second, an analytical method using chromatography columns and conditions that provide the best resolution and reproducibility is developed. An opportunity exists to optimize the analysis based on chromatography, digestion, and LC/MS performance. Finally, the resulting LC/MS data are profiled, according to amino acid sequence, peak number, and $[M + H]^+$. Other properties such as relative retention time can also be added in this format.

IMPURITY IDENTIFICATION IN QUALITY CONTROL

Regulatory authorities strictly scrutinize the leachables (e.g., plasticizers, impurities) that may come from medical devices and drugs. It is the responsibility of the drug or medical device company to identify the leachables and to provide adequate testing of their toxicity. Monitoring methods must be developed and validated to effectively control toxic leachables during the manufacture of high quality pharmaceuticals.

As a result, materials for medical devices and drug products must be tested for leachable components. Once a known toxic compound is discovered, it must be identified for the assessment of toxicity, followed by the monitoring of levels using validated methods as required by the FDA. This identification procedure could be a time-consuming process with traditional methods that are based on fractionation and individual component analysis.

Tiller et al. demonstrated an analytical strategy with on-line LC/UV/MS and LC/MS/MS to rapidly obtain structural information for leachables from a drug-delivery device (76). Similar to proteomics-based applications, the analysis strategy makes use of "data-dependent" analysis, wherein the mass spectrometer first obtains molecular ions using full-scan techniques, and makes real-time decisions about MS/MS product-ion spectra that must be obtained. In this way, molecular weight and substructural information are both obtained for many components during a single HPLC run.

Many components were readily observed from the ESI-LC/MS chromatogram, and several polyester leachables were identified. The ESI LC/MS chromatogram revealed 15 components, compared to the three components that were observed in the 220 nm UV chromatogram. This difference illustrates the capability of ESI-LC/MS to provide a more universal detection when the analytes

Fig. 10 Schematic of an LC/NMR/MS system. In this configuration, NMR is used to provide structural, stereochemical, or ligand binding information while MS is used to provide molecular weight information. (Courtesy of Bruker Daltonics, Billerica, MA.)

do not contain strongly UV-absorbing substructures (e.g., aromatic). The MS-based method proved to be highly efficient because molecular weight and substructural information via the full-scan and product-ion experiments, respectively, could both be obtained for the sample components.

CONCLUSIONS AND FUTURE PROSPECTS

The understanding and application of MS in the pharmaceutical industry has experienced tremendous growth due to unprecedented sample requirements (i.e., trace mixture analysis) and commercial pressure (i.e., faster development time-lines). Today, MS is an essential component of the modern pharmaceutical laboratory as well as an important complement to traditional methods of analysis.

An expanded role for highly sensitive assays for both quantitative and qualitative analysis will likely continue. Novel pharmaceutically relevant formats and systems that expand current approaches as well as create low-flow, miniaturized formats (77–79) are envisioned. Continued advances in integrated approaches that feature MS will generate significant interest with regard to pharmaceutical

analysis. For example, the use of integrated systems that feature NMR/MS have been described for applications that involve LC/NMR/MS (80,81) and MS/NMR (82). A schematic of an LC/NMR/MS system is shown in Fig. 10. In these configurations, NMR is used to provide structural and stereochemical information (80, 81) or to verify binding/interaction (82) while MS is used to provide molecular weight information. New challenges that deal specifically with probing mechanism of action will likely generate the need for a broader application of MS as well as spur the development of novel technologies for sample preparation, chromatography, and information management.

SPECTROSCOPIC METHODS OF ANALYSIS—NEAR-INFRARED SPECTROMETRY

Emil W. Ciurczak

Purdue Pharma LP, Ardsley, New York, U.S.A.

INTRODUCTION

In recent years, there has been an increased interest in near-infrared (NIR) spectrometry. New instrumentation and algorithms have made the technique more powerful yet simple to use. The physics of NIR allow the samples to be analyzed as-is with, essentially, no preparation. NIR absorbance bands originate in the mid-infrared (MIR) region, but absorbencies are far lower (than those in the MIR), detectors are quieter, and light sources are stronger. The depth of penetration of the NIR light is such that pure materials may be analyzed, allowing whole tablets and bulk materials to be assayed quickly and easily.

Near-infrared radiation is the region of the electromagnetic spectrum between the visible and the (traditional) infrared. The nominal wavelengths for NIR are between 650 and 2500 nm (15,400 to 4000 cm^{-1}). The MIR or traditional infrared derives from the fundamental stretching, bending, and rotating motions of the molecule in question. Its wavelength range is between 2500 and 25,000 nm (4000 to 400 cm^{-1}).

Several aspects of a typical NIR spectrum derive directly from the physics of the region:

1. As the absorptivities in the NIR are 10–1000 times lower than that in the mid-range IR, the peaks are concomitantly smaller. This allows concentrated or pure samples to be scanned.
2. All the higher (1st through 6th) overtones of the O–H, N–H, C–H, and S–H bands from the IR are seen in the (much smaller) NIR region. This, in addition to combination bands (e.g., C=O stretch + N–H bend in protein), gives rise to a crowded spectrum with severely overlapping bands.
3. With lower absorptivities, the radiation penetrates deeper into a sample of either a pure material or mixture. Without dissolving, grinding, or diluting with an inert salt, the integrity of the compound is maintained. Thus, crystallinity, polymorphic form, particle size, and ratio or surface to lattice moisture is maintained.

With these differences from the mid-range IR, standard IR and UV/Vis/NIR instruments could not be counted on to produce satisfactory analyses of nonconventional pharmaceutical samples.

HARDWARE

Initially, work in the NIR was performed on instruments primarily designed for ultraviolet or visible analyses. The NIR portion of the spectrum was an afterthought in many instruments commercially available at that time: Beckman, Cary, Coleman, Perkin-Elmer, Shimadzu, Unicam, and Zeiss. The earliest instruments dedicated to NIR were based upon interference filters. The work performed by Karl Norris of the U.S. Department of Agriculture (Beltsville, MD) was initially done on the UV/Vis/NIR instruments mentioned previously. He established a number of important wavelengths associated with grains and other agricultural products. This group of “useful” wavelengths was then used to guide the wavelengths of the filters first used in the NIR instruments. Later, filters were added for tobacco and textile industries.

The first commercial instrument dedicated to NIR was developed by Dickey-John and presented in 1971 at the Illinois State Fair. The technology was licensed by Technicon and introduced soon thereafter. Technicon then developed its own scanning monochromator-based instrument. This was followed by instruments from Pacific Scientific (now FOSS-NIR Systems) and LT Industries, to name a few companies.

In the late 1980s and early 1990s, interferometer-based instruments were introduced by companies already producing IR equipment: Nicolet, Bomem, Perkin-Elmer, and others. Often, these FT-NIR instruments were merely adapted FT-IRs that were already in existence and were not suited for pharmaceutical samples: pure raw materials, blends and granulations, tablets and capsules, and larger plastic containers.

A number of instrument suppliers as well as engineering specialty houses are able to install in-line NIR hardware in

Table 1 Typical applications of NIR in pharmaceutical production

Quantitative	Qualitative

Crystallinity	

production settings. For up-to-date listings and manufacturers, a newcomer (or even experienced user) should scan the Internet, attend meetings such as PittCon, IFPAC, and more specialized conferences such as the International Diffuse Reflectance Conference (Chambersburg, PA on even-numbered years) or the International NIR Conferences (Europe and Asia on various years).

SOFTWARE

Software, per se, was not available for NIR until the 1980s. Technicon (Tarrytown, NY) and Pacific Scientific (Silver Spring, MD) offered software for their scanning monochromator-based (holographic grating) instruments. The software ran their instruments, collected the spectra, and performed simple calculations. At that time, the only algorithms for NIR used multiple linear regression as the core math treatment (“step-up search” and “best-combination”). Spectral treatments such as smoothing and derivatives were available in the late 1980s, but little in the way of “higher math” treatments.

Throughout the 1980s, researchers were developing private software packages for principle components analyses (PCA) and partial least squares (PLS). These matrix-based algorithms have been commercially available for over a decade from the instrument vendors or from third-party vendors. The PCA and PLS algorithms supplied by instrument vendors are more pragmatic and tend to change more slowly than those provided by vendors whose primary function is to provide software. Recently, artificial neural networks (ANNs or NNs) have attracting attention. These are best discussed in a text devoted to the subject and have not yet been used in industrial settings.

Third-party software vendors perform an important part in supplying software for equation development. These vendors exist solely for providing arithmetic tools for the analyst. Instrument vendors are good at providing software to run their instruments and collect quality spectra. The strong point of software providers is their ability to write software solely for analysis. These programs work, in many cases, better than the software instrument companies because they are single-purposed and not multifunctional (i.e., complex and prone to longer development times and, therefore, bugs.) A listing of these vendors would be at best, ephemeral. Large conferences would be the place to start looking for current suppliers.

The first commercial qualitative analysis software was introduced in 1984 (1, 2) by Technicon. Based on Mahalanobis distance, the program used the absorbances of materials at wavelengths chosen by the software to classify them. This was first applied to incoming raw materials. Since then, virtually every manufacturer of hardware also supplies software capable of performing either qualitative or quantitative analyses. As will be touched on in applications, identification and quality assessment of incoming raw materials is commonplace in the industry.

APPLICATIONS

Owing to the late development of fast, small, and inexpensive computers, little work was performed on pharmaceutical samples until the 1980s. In 1966 (3), many pharmacologically active amine salts were investigated both in solid state and in solution. Two drugs were quantified in 1967 (4): allylisopropylacetureide and

phenacetin were dissolved in chloroform and simultaneously quantified at 1983 and 2019 nm, respectively.

Water was determined in several matrices (5) in 1968. Solid samples were analyzed for hydrous and anhydrous forms of strychnine sulfate, sodium tartrate, and ammonium oxalate mixed with KCl and compressed into disks containing 100 mg KCl and 25 mg drug. The water band at ~1940 nm was used for the hydrate analysis.

Since the middle 1980s, there has been an ever-expanding list of applications, both qualitative and

quantitative, of NIR in pharmaceuticals. These applications are as follows:

1. Particle Size. Since the first reports of particle size measurement by NIR in 1985 (6) and 1986 (7), numerous researchers have reported using NIR for particle size assessment, both in pure samples and mixes (e.g., 8, 9).
2. Hardness. As NIR spectra are affected by physical and chemical changes within a sample, physical parameters such as hardness may be measured. In 1997, a paper by Morrisseau and Rhodes (10) was published wherein hardness from 2 to 12 kg was estimated by NIR. Several other workers have reported success in measuring hardness: Ebube et al. in 1999 (11) and Kirsch and Drennen (12) have done some quality work on the topic.
3. Polymorphism crystallinity. One of the earliest reported uses of NIR for polymorphism was for the polymorphs of caffeine in 1985 (13). In 1987, Gimet and Luong (14) used NIR to ascertain changes in crystallinity during processing.

Differentiation between polymorphs was performed by pattern recognition in 1995 by Aldrich et al. (15). The actual control of a process was reported in 1998 by DeBraekeleer et al. (16), where they described using PCA, SIMPLISMA, and orthogonal projections to correct for temperature variation during the monitoring of polymorph conversion. This is a real-time, in-line procedure.

Several recent papers have also highlighted NIR for polymorphism (17–20). The advantage of NIR for reading polymorphic changes is that the C–C, C–O, and other non-H bonds are not visible. The N–H and O–H bands dominate the spectrum, making crystal changes obvious for qualitative analysis.

4. Enantiomers/structural isomers. The particular optical isomer of a drug being used in a formulation is quite important. For example, quinine is used to treat malaria; quinidine, its optical isomer, is used for heart arrhythmia. In 1985, Ciurczak (21) observed that although pure D- and L-amino acids gave identical spectra, the racemic mixtures (DL-) produced an entirely different spectra. Some work was presented by Ciurczak (22) in 1986, which was later expanded and published (23) by Buchanan et al. in 1988, where the enantiomer ratio was determined via NIR.

Mustillo and Ciurczak (24) presented a paper discussing the spectral effect of optically active solvents on enantiomer mixes. This information was used as a technique to screen for polar modifiers in normal-phase chromatography of racemic mixtures (25).

In 2000, the enantiomeric composition of ibuprofen in solid-state mixtures was performed by Agatonovic-Kurstin et al. (26).

Structural or geometric isomers as well as nearly identical molecules may be discriminated by NIR. Some early work was performed by Kradjel and Ciurczak (27) and presented in 1985. Work has been performed where the type of polyvinylpyrrolidone is determined by NIR (28). The only differences between types are polymerization conditions.

5. Identification Quality Assessment. In a first of its kind paper, Rose in 1982 showed that a number of structurally similar penicillin-type drugs could be identified and determined by NIR. (29). At Sandoz, Ciurczak in 1984 reported using Mahalanobis distance-based algorithms for the identification of raw materials (30). Ciurczak also reported the use of spectral matching (SM) and principle component analysis (PCA) for raw materials (31) and suggested a method for introducing variations into samples for more robust equation development in 1986 (32). NIR has been in use for raw material ID since then in companies worldwide.
6. Blend Uniformity. An early presentation (33) of the potential for following a dry blend through its stages of mixing by Ciurczak was expanded and published in 1990 (34). A fiber probe was used on a mixture, probing at several locations to several depths. The spectra were then compared with a fully blended sample, using both a SM and a PCA program.

Another similar paper was published by Blanco et al. in 1999 (35). They also used a fiber optic probe on stopped blenders and showed for yet another blend that NIR is a useful tool. Further work was reported on blend uniformity in 1996 by Drennen et al. (36), where samples were sieved and assayed for hydrochlorothiazide by reflection NIR.

Workers at Pfizer patented an automated system specifically designed for a "V-Blender." Its development is described in 1996 in a paper by Sekulic et al. (37). This design calls for a single-fiber probe to be permanently inserted in the shaft of the blender. This device was used by DeMaesschalck et al. in 1998, and a paper was published in this work. The significance of this paper was that workers outside Pfizer also used this device successfully.

A study that used both ports along the body of a blender and a two-dimensional imaging technique to measure homogeneity is described in (38). This approach uses multiple measurement points and the speed of NIR. The paper also describes a two-dimensional imaging of the surface to assess uniformity.

Papers by DeMaesschalck et al. (39) and Bemtsson et al. (40) are significant in that they discuss the mathematical treatments involved in following blend uniformity and in-line analysis of active.

7. Moisture. In NIR, as in the MIR, water has the strongest absorption of light. It stands to reason that moisture in solid products would be an important assay. For instance, Warren et al. (41) used NIR to determine the amount of water in glycerides. Transmission spectra of standard propylene glycol and glycerin were used to calibrate and measure for the water content.

Correlation of total, bound, and surface water in raw materials was the topic of a paper by Torlini and Ciurczak in 1987 (42). The NIR was calibrated by Karl Fischer titration, differential scanning calorimetry (DSC), and thermal gravimetric analysis (TGA) for the various water types. NIR could distinguish surface from bound water, whereas standard loss on drying (LOD) could not.

In a recent paper, Derksen et al. (43) showed how NIR could be used to determine the moisture content through the glass vials for freeze-dried samples with varying amounts of active.

In-line moisture of a granulation was discussed by Rantanen et al. (44) in 2000. A binder was added in a solution and the granulation evaluated for residual moisture. Derivatives were used to minimize the particle size effects. Although the measurements were performed (initially) with a full scanning instrument, the authors were able to use fixed wavelength instruments for routine usage. This is an important introduction to simple process control.

Ciurczak discusses similar simple mono-wavelength devices in a recent article (45), where he shows "spark plug" type of mini-infrared source-detector combination. This device should soon be available in the NIR range for similar applications.

8. Clinical Supplies. A rapidly growing use for NIR is the discrimination between clinical dosage forms and placebos that are made to look identical to them. Normally, unmarked tablets or capsules are arranged in a specific manner in blister packs. The identity of which is the active is kept from both the patient and the attending doctor (thus the term "double-blind").

An early application of NIR to clinical samples was published by Aldrich et al. (46) in 1994. Using a custom fiber optic assembly, samples were scanned directly through the polymeric material of the blister packs. This demonstrated the power of discrimination of NIR.

In two papers, Ritchie et al. (47, 48) described an approach for performing NIR qualitatively with an eye

to cGMPs (current good manufacturing practices). As clinical lots are often ad hoc formulations, it is difficult to gather enough lots to generate a discriminant equation prior to an actual clinical trial. They developed a procedure whereby equations are quickly generated for a particular study, based on that placebo and active, used for the study, then discarded. Thus, a full validation procedure is shortened to half-day per study.

9. Content Uniformity/assay. The question most often asked is when NIR will be able to be used as a release test. In the earliest NIR assays, tablets and capsules were not analyzed intact. Prior to scanning, the active was extracted and scanned in a clear liquid. The first use of NIR for tablets was reported in 1968 (49). Sherken assayed the meprobamate content in tablet mixtures and commercial preparations. Allen (50) used NIR to analyze a three-component mix: carisoprodol, phenacetin, and caffeine. The powder was extracted with chloroform and scanned in the NIR. Several other publications took advantage of the "dissolve and scan" approach (51, 52).

The first published analysis for powders was written in 1981 (53) by Beconsall et al. It described the analysis of propranolol and magnesium carbonate mixes. In 1987, Ciurczak and Torlini (54) published on the analysis of solid and liquid dosage forms using reflectance and transreflectance, respectively.

In 1987, Chasseur assayed cimetidine granules (55). This was the first reported use of a synthetically produced extended range for calibration; calibration samples were produced with a range of content from 70 to 130% of label. In 1987, Osborne (54) used NIR to assay for nicotinamide in vitamin premixes.

In 1988, Jensen et al. used NIR to analyze amiodarone tablets (57). The approach was somewhat primitive: the tablets were scraped of their coating and glued to an aluminum plate. Reflectance was used and six wavelengths were needed to analyze the tablets.

Two chapters of collections were published in the early 1990s wherein solid dosage form analysis was discussed. Based on a presentation at the Fourth International Conference on NIRS (58), Stark used a newly developed diode-array spectrometer scanning between 520 and 1800 nm to analyze specimens. Samples were placed on glass slides and the light collected at a fixed angle. Intact acetaminophen, ibuprofen, and antacid tablets were collected.

In a second chapter (59), Monfre and DeThomas wrote about the calibration of a NIR instrument for the analysis of a prescription vasodilator. Individual tablets were used, but still needed to be crushed for analysis. The important

part of the calibration was that no synthetic tablets were produced to extend the range. Using only production tablets ranging from 96% to 102% of label claim, the NIR results were within 0.5 mg of the HPLC values.

Borer et al. used NIR to evaluate the key sources of variation in tablet analysis in 1998 (60). The effects of active variation as well as instrumental variations were evaluated statistically. Factors such as the opening (light beam width), derivative segment size, days between measurement and calibration of the instrument, and tablet orientation were found to be significant. This study tends to affirm the value of transmission measurements where the tablet orientation and optical configurations are fixed.

NIR was used to determine the effects of changes in magnesium stearate concentration and variations in compression pressure on tablet analysis (61). Various types of Avicel (microcrystalline cellulose), varying mostly in particle size, were compressed into tablets with or without magnesium stearate as lubricant by using various compression pressures. Various mathematical treatments were used to either measure the differences or obviate their effects on the analysis.

CONCLUSIONS

The above list of applications is not intended to be a comprehensive listing of all workers or findings in the field of NIR. Rather, it is an overview and can be used as a starting point for informational purposes. By performing a citation search on the authors cited here, the people who have used their work as a basis of current research can be known and will give the analyst an extended list of authors to follow-up for additional discoveries.

SPECTROSCOPIC METHODS OF ANALYSIS—ULTRAVIOLET AND VISIBLE SPECTROPHOTOMETRY

R. Raghavan
Jose C. Joseph

Abbott Laboratories, Abbott Park, Illinois, U.S.A.

INTRODUCTION

Many compounds of pharmaceutical interest are colorless. In the early part of the 20th century, analytical methods were developed using color-forming reactions and measurement of color for quantitation. With the development of instrumentation and based on an understanding of optics, ultraviolet and visible spectrophotometric techniques advanced further. However, with rapid development of atomic absorption spectroscopy, plasma atomic spectroscopy, and GC and HPLC techniques, the interest in spectrophotometry waned in the late 1980s and in 1990s. HPLC methods and HPLC instruments advanced further. As a result, rapid scan techniques and microprocessor control of such instruments led to the development of sophisticated UV–vis spectrophotometric detectors. With renewed interest in the application of UV–vis spectrophotometric techniques, a whole new generation of spectrophotometers with microprocessor instrument control, data acquisition, data handling, and data smoothing are currently available.

BASIC CONCEPTS AND DEFINITIONS

Electromagnetic Radiation

Spectrophotometry involves the measurement of the chemical species using light energy. Light is a form of radiation called electromagnetic radiation. Electromagnetic radiation spans a very large region involving very low energy waves (<0.0012 kJ/mol) to extremely energetic cosmic radiation ($>1.2 \times 10^8$ kJ/mol). This energy can be related by the equation $E = h\nu$, where h is a constant known as Planck's constant (equal to 6.62×10^{-24} J/s), ν is the frequency, which is related to the velocity of propagation of radiation as waves; and $\nu = c/\lambda$, where λ is the wavelength of radiation, which is the distance between either of two crests or two troughs of such a wave. Electromagnetic radiation is continuous; however, it is separated into different regions with differing energies.

The instruments and techniques needed to measure radiation are different in different regions of radiation. It should be noted that this artificial separation resulted from historical development of understanding radiation phenomenon. Table 1 lists the different regions of electromagnetic radiation.

The human eye responds to radiant energy between 150 and 310 kJ/mol (350–780 nm, wavelength). For each color observed, there is a complementary color; this complementary color corresponds to the wavelength of light that is absorbed by the material. Table 2 shows the approximate relationship between color characteristics and wavelength. The wavelength region of interest for pharmaceutical analysis is between 200 and 800 nm (UV and visible region).

Absorption of Light

When light of a particular wavelength passes through a dilute solution in an appropriate container (quartz, glass, or plastic cells), the light may interact with matter in a number of ways. A portion of the light may be absorbed and the rest passed through unaffected but redirected. The redirection phenomenon is known as scattering. The absorbed energy may be emitted with energy of lower wavelength. This process is known as emission. In UV–vis spectrophotometry, the difference between the incident and emerging beam of light is measured. This property, known as absorption, is used in quantitative and qualitative characterization of molecules of pharmaceutical interest. If the intensity of an incident beam of radiation is monitored and compared with that of an emerging beam, there is attenuation in the emergent beam. This attenuation is caused by 1) reflection at the air/cell surface interface; 2) absorption by the cell wall; 3) reflection at the cell/liquid interface; 4) absorption by solute; 5) absorption by solvent; 6) scatter by solution; and 7) refraction or dispersion by cell.

Therefore, to observe only the effect caused by the substance of interest, all other factors have to be eliminated. This is normally achieved by the use of two matched cells. By comparison of the energy of the incident

Table 1 Electromagnetic spectrum

Radiation (rays)	≈Frequency (Hz)	Wavelength (m)	Energy (kJ/mol)
Cosmic rays	$>10^{20}$	$<10^{-12}$	$>1.2 \times 10^8$
Gamma rays	$10^{19.5}-10^{20}$	$10^{-12}-10^{-11}$	$1.2-12 \times 10^7$
X-Rays	$10^{16.5}-10^{19.5}$	$10^{-11}-10^{-8}$	$12,000-1.2 \times 10^7$
UV	$10^{15}-10^{16.5}$	$10^{-8}-0.38 \times 10^{-7}$	310–12,000
Visible	$10^{14.6}-10^{15}$	$0.38 \times 10^{-7}-0.8 \times 10^{-7}$	150–310
Infrared	$10^{11}-10^{14.6}$	$0.8 \times 10^{-7}-10^{-3}$	0.12–150
Microwave	10^7-10^{11}	$10^{-3}-10^{-1}$	0.0012–0.12
Radio	$<10^7$	$<10^{-1}$	<0.0012

and emergent beams from these matched cells, the extent of light absorbed by the sample of interest (or analyte) can be expressed in terms of a quantity called “absorbance.”

Beer Lambert’s Law (or Beer’s Law)

Instruments used for UV–vis spectra measure the intensity of incident (I_0) and emerging light (I). It is related to absorbance as follows: $A = -\log(I/I_0) = -\log(T)$. T is called transmittance. The instruments can display data as either percent of transmittance or, more commonly, as absorbance A . According to Beer’s law, absorbance is proportional to the concentration of the absorbing species and the length of the path through which light travels: $A = abc$, where a is a constant called the absorption coefficient or absorptivity; a is dependent on the wavelength and the unit of concentration, c , and b is the path length in centimeters. When c is expressed as mol/L (M) $A = \epsilon bc$, where ϵ is called the molar absorptivity. Beer’s law is applicable under the following conditions:

- The incident radiant beam is monochromatic (monochromatic light is light of a single wavelength or better, light of a wavelength within a very narrow range, in terms of what is experimentally feasible).
- The incident radiation travels through equidistant parallel paths through the sample.
- There is no chemical reaction occurring followed by absorption of radiant energy.
- The sample solution is homogeneous and, thus, there is no loss of radiant energy through scattering or by other reflection processes.
- Each molecule absorbs independently and is not affected by other molecules in solution. (Note: This may not be true for high solute concentration).

The common terms, symbols, and definitions of terms, per International Union of Pure and Applied Chemistry (IUPAC) in absorption measurement are given in Table 3.

Applicability of Beer’s Law

The direct proportionality between absorbance and concentration for a fixed path length must be established experimentally for a given instrument under specified set of conditions. If this relationship is linear within the specified range of concentrations, the system is said to obey Beer’s law. Departure from this direct proportionality arises from both instrumental and chemical reasons.

In Beer’s law, c is the total analytical concentration of the absorbing species in a particular molecular state. If there is a disturbance in the concentration of this particular species as a function of solvent concentration, these deviations can be eliminated by appropriate choice of experimental conditions.

Sometimes, in organic acids and bases, the extent of hydrolysis or ionization can be affected as a function of pH. Then, the pH of the analyte should be chosen such that it is

Table 2 Visible spectrum characteristics

Wavelength (nm)	Color absorbed	Color observed
380–420	Violet	Green-yellow
420–440	Violet-blue	Yellow
440–470	Blue	Orange
470–500	Blue-green	Red
500–520	Green	Purple
520–550	Green-yellow	Violet
550–580	Yellow	Violet-blue
580–620	Orange	Blue
620–680	Red	Blue-green
680–780	Purple	Green

Table 3 Spectrophotometric nomenclature (IUPAC)

Name	Symbol	Definition
Transmittance	T	P/P_0
Absorbance	A	$\log_{10} P/P_0$
Path length	b	—
Absorptivity	a	A/bc^*
Molar absorptivity	ϵ	$A/bc^\#$
Wavelength unit	nm	10^{-9} m
Absorption max	λ_{\max}	Wavelength of maximum absorption

b is in cms; c^* units other than moles per liter; $\#$ moles per liter. Other terms used in the older literature are given in Raghavan and Joseph (1997) under Bibliography.

three units more or three units less than the pK_a of the monoprotic acid. Otherwise, the absorbance measurement can be made at a wavelength at which molar absorptivities of both species are identical. The wavelength at which the absorbencies are identical is known as isosbestic point. At this wavelength, the molar absorptivity of the two species is the same and, thus, measurements at this wavelength do not deviate from Beer's law. At millimolar concentrations at which absorbance measurements are made, the refractive index of the sample and that of the reference do not differ considerably. However, if the concentration is increased, as in derivative spectrophotometry, refractive index may be altered and, as a result, deviation from Beer's law may become significant. The second type of deviation from Beer's law occurs under derivative and dual wavelength spectrophotometric conditions. Deviation from Beer's law is negligible if:

- instrumental deviations are minimal;
- the solvent absorption is negligible in comparison with the analyte absorbance;
- the analyte concentration is within a specified range;
- there is no chemical interaction between solute molecules or between solute and solvent molecules; and
- the temperature is maintained constant, especially for flow injection analysis and reaction rate measurements.

Deviations from Beer's law caused by instrumental parameters are discussed later.

COMPONENTS OF THE SPECTROPHOTOMETER

List of Instrument Components and Functions

A spectrophotometer measures the change in light intensity when light passes through a liquid sample or

other medium. Therefore, appropriate light source(s) is needed. The light source gives out radiation consisting of a whole range of wavelengths and different intensities. Therefore, these different wavelengths should be separated. The light thus separated has to be passed through the analyte sample. To monitor the emerging beam, knowledge of incident beam is gathered from a reference solution containing all the matrix elements except that of the analyte. The emerging light needs detection, and an appropriate display system is needed for proper presentation of data. These different components and their functions are presented briefly in Table 4.

Light source

Two light sources, one for each region, are commonly used. For the visible region, a tungsten filament lamp sealed inside a quartz envelope containing a small amount of iodine is used. The source is operated at 3500 K. This type of lamp has excellent stability and a useful life of more than 10,000 h. For the entire UV region, a deuterium arc discharge lamp is used. This lamp consists of a quartz envelope filled with deuterium gas at a pressure of <0.01 atm (2–3 mm) and two electrodes separated by a small distance. When electrically discharged by passing a current through the electrodes, light is emitted as a result of ionization of gas and produces a continuous emission spectrum below 375 nm. This lamp has a useful life of more than 1000 h. A typical spectrophotometer contains both types of lamps, with a mechanical source selector that automatically switches between the two lamps as necessary. (It should be noted that mercury-vapor lamps are normally used as light sources for UV detectors of high-performance liquid chromatographs. Because a majority of organic compounds of pharmaceutical interest absorbs at 254 nm, and this lamp has an intense line spectrum at 253.7 nm, this lamp finds wide use in HPLC detectors).

Monochromators and filters

In forward optic spectrophotometers, electromagnetic radiation of a specified wavelength is passed through sample solutions. Because radiation from source is polychromatic (consists of light of all wavelengths), the various wavelengths of radiation must be separated within a narrow range to form a monochromatic beam before it is passed through the cell and directed on to the detector. Two types of wavelength selectors are used. These are 1) filters, which provide a limited wavelength selection with a high bandwidth, and 2) monochromators, which provide continuous variation of wavelengths with narrow bandwidths. Monochromators serve two basic functions, namely, they isolate the narrow bandwidth of wavelengths very close to the specific

Table 4 Components of a spectrophotometer and their functions

Component	Functions of the component
Power supply	Regulates and provides constant power needed for the light sources
Light source	Provides electromagnetic radiation over a range of wavelengths; the intensity may vary as a function of wavelength
Monochromator	Selects a narrow band of wavelength of choice
Entrance and exit slits	These slits are part of a monochromator to select a narrow beam of light
Sample port	This port accommodates a cell containing sample analyte and any other reference cells
Detector	The detector consists of a photosensitive device, which converts radiation energy into electrical energy yielding an output signal; this may consist of electronic circuitry and microprocessors and other components to amplify the initial signal received from the radiant energy
Digital read-out/computer	The digitized signals from the detector are stored in a computer for data-handling and for graphical display or print-out later

(selected) wavelength and automatically adjust exit slits such that the intensity of the light at the chosen wavelength is maximum, and light of other wavelengths is minimal or preferably, negligible. In addition, the monochromator lends itself to rapid scans of the entire spectral region of interest. The monochromator is a system consisting of combinations of lenses, a dispersion device (a prism or more commonly a grating), slits, and filters.

The entrance and exit slits of a monochromator isolate narrow portions of the light beam and direct them on to the grating. The slit width may be varied automatically by instruments to increase or decrease radiant power reaching the sample and detector. The grating is automatically driven by what is called a sine-bar mechanism, in which the bar that holds the grating is attached to a stepper motor-driven micrometer screw. Thus, the instrument covers a range of approximately 200–900 nm, with wavelength variation of ± 0.2 nm.

The grating is used to split polychromatic light into a series of monochromatic radiation of selected wavelengths. The diffraction grating used in UV–vis spectrophotometer is a very simple optical device that consists of parallel grooves. Most gratings in spectrophotometers are prepared holographically by coating a flat glass plate with a photosensitive material. An interference pattern is then generated by the use of laser beams. When the photosensitive layer is developed, glass plates are left with perfectly grooved patterns. To make the grating reflective, a thin film of aluminum is vacuum-deposited on its surface. A protective layer of silicon dioxide is deposited on top of this aluminum layer to keep it from tarnishing. Given the use of lasers, and holographic techniques, a precision level of <0.001 nm can be attained for these gratings.

When polychromatic radiation is incident upon the grating, it is rotated, resulting in a specific wavelength of light being allowed to pass through the slit and then onto the sample or detector depending on the nature of the spectrophotometer. Such rotation of the grating results in scanning a series of wavelengths each time with a specified wavelength. Thus, polychromatic light is split into monochromatic light. Gratings, therefore, provide stable, parallel, and highly monochromatic light, and stray radiation is greatly reduced in holographically generated grating monochromators. For UV–vis spectrophotometers, the gratings used normally have 1000–3000 lines per millimeter. Thus, a single grating, as a dispersion device, is adequate to cover the entire range between 200 and 900 nm.

Cells

Sample cells are available in a variety of shapes and sizes that can be used for many different applications. The most common is a rectangular-shaped cell, made of quartz, with dimensions of $12 \times 12 \times 45$ mm, with an inside length of 1 cm, and holds approximately 4 ml of solution. Cylindrical cells are normally 20 mm in diameter with a path length ranging from 5 to 200 mm. Because glass and plastic materials absorb in the UV region, quartz cells are required for measuring spectra below 340 nm, but cheaper glass cells or disposable plastic cells are adequate for the visible region. Cells with built-in water jackets are available for maintaining constant temperature for kinetic studies. Flow-through cells for flow injection and HPLC applications typically have cell volumes between 0.5 and 2 μ l, with a path length of approximately 1 cm. For limited samples, typically with a cross-sectional area of 2×2.5 mm, holding at least 60 μ l of sample is available. With special ultramicrocells, samples volume as low as 5 μ l can be used.

The cell windows should be maintained clean with no scratches and adhering liquids. The placement of the cuvettes is very important. Otherwise, cell walls can block the radiation beam, resulting in irreproducible erroneous results. Cells should always be stored in matched pairs, dry, and preferably inside a protective container. Catalogs provide figures and a list of the different types of cells available commercially.

Detectors

A detector is a device in which light intensity is transformed into an electrical signal. An ideal detector should have the following characteristics:

- high sensitivity irrespective of wavelength;
- very low drift in sensitivity, if any, over the entire wavelength range;
- high signal-to-noise ratio;
- no dark signal (or, if any, it should be very low);
- rapid response time;
- linear response to radiant power; and
- ease in calibration and standardization.

Even though no detector meets the entire criteria, many commercially available instruments, come very close to ideal with respect to performance characteristics.

Typically, light is allowed to fall on a metal coated with a light-sensitive substance. When light falls on this substance, electrons are released. By maintaining a potential difference of approximately 100 V, the released electrons from the cathode travel to the anode, producing a photocurrent. The resulting photocurrent thus generated is proportional to the intensity of light and is amplified, digitized, and measured. The measured current is plotted as a function of wavelength. However, in a majority of spectrophotometers, photomultiplier tubes are used to produce secondary amplification. The secondary amplification is produced such that for every primary electron generated, secondary electrons are attracted to a secondary electrode called a dynode. By using 8 to 10 dynodes, that are suitably oriented, connected in series, and having increasing positive potential, a million-fold amplification in photocurrent is attained. Very efficient silicon diodes are also used in many newer instruments.

Semiconductor silicon diodes

Semiconductor silicon diodes, called photodiodes, with special conductance properties are generally used in diode array spectrophotometers. Photodiodes are very useful because scan times of the order of a few milliseconds and thus many scans may be obtained in a very short time. In addition, the data obtained, being digital, can be further

processed to generate spectra with a very high degree of resolution and accuracy.

Charge coupled device detectors

These solid state detectors are multichannel devices. They have large number of photon-detecting registers. The registers are semiconductor capacitors that have been formed on a silicon chip. These detectors, which can detect very low levels of light, are primarily used in probe-type, near-infrared, and visible spectrophotometers and in fluorometers.

Read-out devices

The electrical signal from the detector is fed into an instrument with read-out capabilities. These read-out systems may be direct-reading or null point systems. In direct-reading systems, the output of the detector is allowed to drive a sensitive meter. In the null point systems, the detector output is balanced by a reference circuit. Because of the imbalance in the current, a servomotor is activated, and this stops when the two circuits are balanced. The extent of movement of the motor directly gives a digital readout. Most popular digital read-out device provide a visual numerical display using light-emitting diodes or tubes. These are directly controlled by the signal from the detector. These digital read-out devices have very rapid response. Current spectrophotometers and photometers are microprocessor-controlled instruments with digital read-out capabilities.

INSTRUMENTATION

The components of a spectrophotometer can be arranged in one of two ways as shown in Fig. 1.

The two arrangements differ only in the relative arrangement of the sample and the monochromator. However, the complexity, the quality, and the speed at which data are acquired and presented are very different. A brief account of these is given below.

Forward Optic Spectrophotometers

Forward optic spectrophotometers are either single-beam or double-beam spectrophotometers. The single-beam instruments can be either very simple or expensive depending on the sophistication desired or needed. Simple single-beam instruments have poor stability and excessive drift. These advantages are eliminated in systems equipped with a high-resolution monochromator with adjustable slits, controlled by microprocessors for rapid data acquisition and evaluation of data.

Fig. 1 (a) Components of a typical UV-vis spectrophotometer (forward optics). (b) Components of a reverse optics spectrophotometer.

There are two different types of double-beam systems. One such double-beam system, referred to as a double-beam-in-time, is shown in Fig. 2a and the other, known as double-beam-in-space, is shown in Fig. 2b.

In the double-beam-in-space system the components of a single beam are exactly duplicated except for the light source. In this system, the primary light beam is split into two beams with a mirror. One of the beams passes through a reference cell containing the solvent alone, whereas the second beam passes through the sample cell. The signal from the detector of the reference cell is subtracted from that of the sample cell, and the absorbance is plotted against the wavelength.

The dual-beam, single-deflector system is referred to as a double-beam-in-time spectrophotometer. In this

system, the primary beam is split into two beams by a mechanical chopper; the chopper is a rotating wheel with alternate silvered and cut sections. The rotating chopper, in addition to splitting the beam, introduces a dark beam into each beam so that the detector records a series of alternating dark-reference dark-sample signals. Using an appropriate chopping frequency and a synchronizing signal, the three signals are measured within 10–50 ms. As a result, this configuration, more easily being amenable to microprocessor control, is used in many rapid scan spectrophotometers.

The double-beam instruments compensate for

- fluctuations in the radiation output signal;
- drift in the detector and amplifier; and

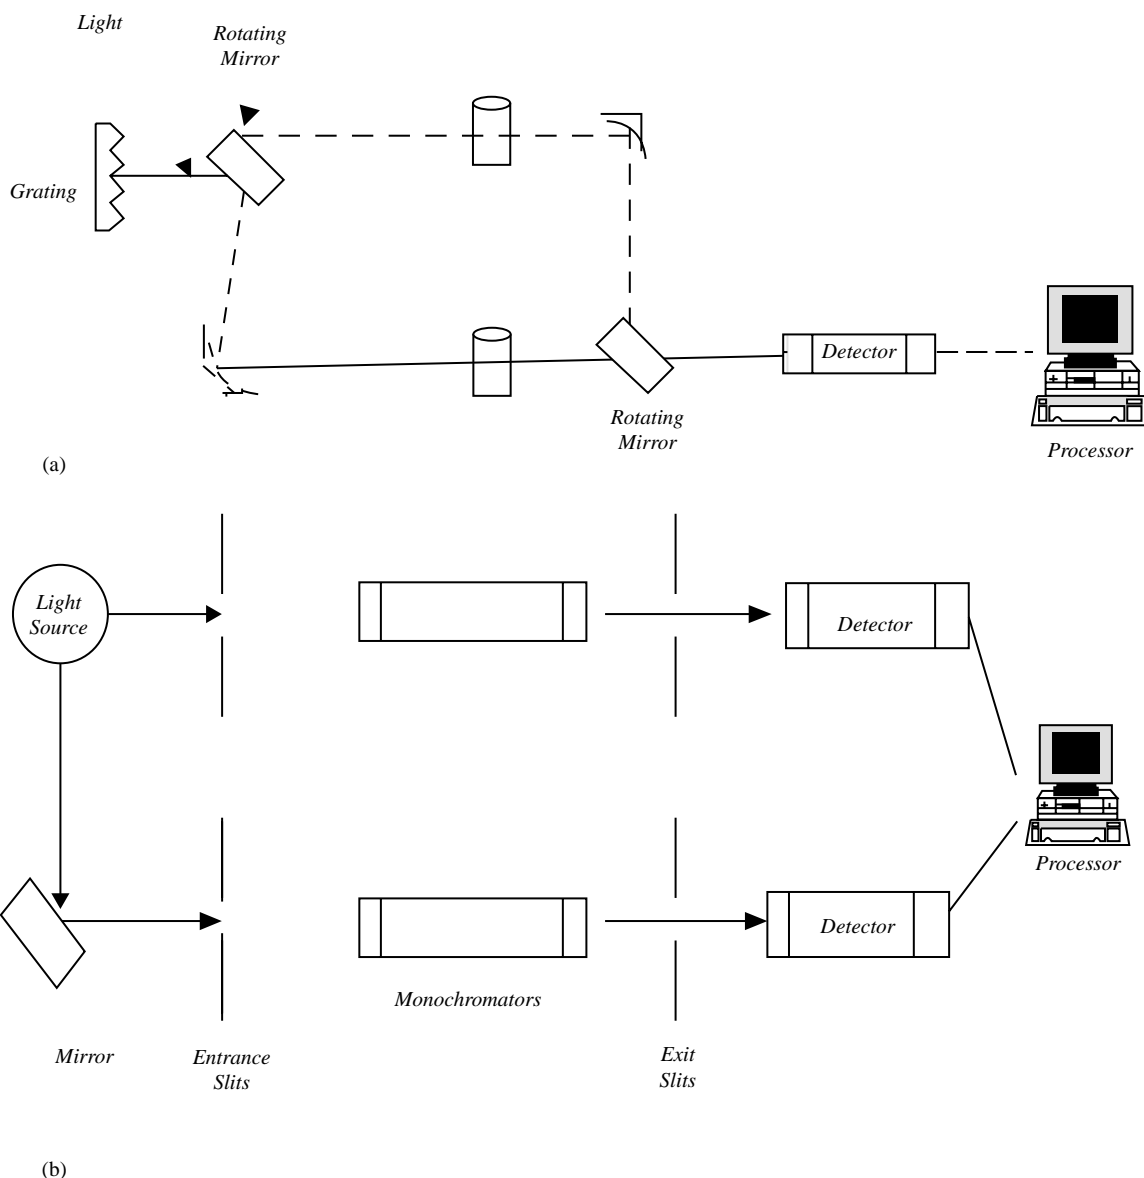

Fig. 2 (a) Block diagram of a double-beam-in-time spectrophotometer (single-detector system with a beam-splitter); a chopper motor can be used in place of the mirror. (b) Block diagram of a double-beam-in-space spectrophotometer.

- wide variations in the intensity of the light source as a function of wavelength.

Reverse Optic Spectrophotometers—Photodiode Array Detectors

The photodiode array detectors are based on reverse optics as shown in Fig. 1b. In this mode, a pair of vibrating mirrors passes the polychromatic light through either the reference cell or the sample cell. The emerging light

dispersed by a dispersion grating (in the monochromator) reaches the diode array detector consisting of a linear array of miniature diodes. The number of such photodiodes may vary between 256 and 4096 per array, with 2048 being the most common. Many such diodes can be formed along the length of a silicon chip. Typically each chip is 1- to 6-cm long, and the widths of the individual diode may vary from 15 to 50 μM . The monochromatic slit width is adjusted to correspond to the width of one of the silicon diodes. Therefore, the output signal of each diode corresponds to

Fig. 3 Schematic of a photodiode-array detector.

the radiation of a different wavelength. By scanning the output of each diode sequentially, a spectrum can be obtained. Because the electronic processing is very rapid, the entire spectrum in a specified range can be acquired in less than 5 ms. The analog signals from the photodiodes are digitized and transferred to a computer. Many different types of multichannel detectors and other diode array detectors are commercially available. These rapid scanning detectors are used for

- analysis of multiple components in a mixture;
- following reactions pathway of short-lived intermediates in reaction kinetics;
- process control by continuous monitoring;
- measuring the dissolution rate of tablets; and
- obtaining spectra of a mobile solution (detection in HPLC).

These new instruments containing several microprocessors with appropriate hardware and software control the following:

- autosampling, which involves loading cell holders and measuring number of samples sequentially;
- automatic mixing, adding reagents, if necessary, diluting, and other sample preparations;
- setting up operating conditions such as selecting a lamp, filter, wavelength drive, and data acquisition mode;
- controlling autocalibration, automatic baseline noise storage, and baseline subtraction;
- multiple data handling characteristics such as spectrum smoothing, data graphical display, and data and peak expansion;
- addition and subtraction of spectra, creation of overlapped spectra for comparison and the like;
- control-associated hardware peripherals such as printers, plotters, etc.; and
- self-test procedures and record keeping of lamp use, maintenance records, etc. to comply with GLP regulations.

PERFORMANCE PARAMETERS OF A SPECTROPHOTOMETER

Specification and List of Parameters

The performance of a spectrophotometer is dependent on a number of parameters that affect the quality of the data, namely, wavelength accuracy, photometric (absorbance) accuracy, spectral bandwidth variations, extent of stray light, and linear response of the instrument. The performance parameters can be evaluated from the specifications provided by the manufacturer. A standard list of specifications of a typical double-beam spectrophotometer is provided in Table 5.

A brief outline of the specification terms, the values of which determine the performance parameters of the instrument, are presented below.

Wavelength Accuracy and Wavelength Calibration

The wavelength accuracy corresponds to the accuracy with which wavelengths measured in different instruments can be compared. In many spectrophotometric procedures, the analyte is quantitated by comparing the absorbance of the analyte with that of a reference standard. The standard is usually prepared at virtually the same concentration of the analyte and absorbance measured at the λ_{\max} of the chromogenic species. This approach is satisfactory for most filter photometers because comparisons are made at a fixed wavelength and with the same spectral bandwidth. However, when continuous choice of wavelength is available, as in many grating spectrophotometers, the accuracy and reproducibility of wavelength as well as the intensity of analyte absorbance have to be verified. This is accomplished by wavelength calibration. For wavelength calibration, holmium oxide glass, usually supplied by the instrument manufacturer, is used. Holmium oxide glass, when scanned between 280 and 650 nm, give very short principal peaks at 241.5, 279.3, 287.6, 333.8, 360.8, 418.5, 536.4, and 637.5 nm. Wavelength accuracy can also be checked using the emission lines from a low-pressure mercury source or deuterium lamp. The spectral bright lines used for this check are 486.0 and 656.1 nm.

For broader bandpass filters, neodymium glass filters are available for additional wavelength calibration in the visible region. Special NIST reference materials referred to as SRM (standard reference materials) numbers are available for calibration and verification from the National Institute of Standards and Technology. Information about these standards can be accessed

Table 5 Standard list of specifications for a typical spectrophotometer

Specification	Typical value for a double-beam instrument
Wavelength range (nm)	190–900 nm
Wavelength accuracy (nm)	± 0.3 nm at slit width of 0.2 nm
Wavelength repeatability (nm) ^a	± 0.1 nm
Wavelength scanning speed	Fast, medium, slow, and super slow
Bandwidth (nm)	0.1–7.5 nm (variable and selectable)
Resolution (nm)	± 0.1 nm
Stray light (%)	$<0.015\%$ at 220 and 340 nm $<0.0003\%$ at 220 and 340 nm (drift instrument)
Photometric accuracy (AU) ^b	± 0.002 in 0–0.5 AU ± 0.004 in 0.5–1.0 AU
Photometric repeatability ^c	± 0.001 in 0–0.5 AU (with NIST 930 D filter)
U (AU)	± 0.002 in 0.5–1.0 AU $\pm 0.3\%T$ (0–100% <i>T</i>)
Photometric mode	Absorbance (Abs), transmittance (%), reflectance (%), and energy (E)
Base-line correction	Selectable with storage firm ware
Drift (AU/h)	<0.0004 after warm up
Response time or time constant	≈ 0.1 –5 s
Photometric range (AU)	–4.0–5.0
Baseline flatness ^d (AU)	Within ± 0.001 Abs
Scan speed	50 nm/min to ≈ 2100 nm/min

^aWavelength repeatability is a measure of the precision of the wavelength measured.

^bAU = Absorbance units.

^cPhotometric repeatability refers to the precision of measured absorbance especially using a standard.

^dBaseline flatness refers to the average deviation from 0.0 AU for a blank versus blank spectrum in the wavelength range in which the spectrum is taken. *Note:* This may be dependent on scan speed.

directly from the Internet (<http://www.i-nist.gov/itl/div898/index.html>).

Wavelength Repeatability and Bandwidth

Spectral Bandwidth (SBW)

Wavelength repeatability is a measure of the precision of wavelength measured. The bandwidth refers to the width of an emission band (from the monochromator) at half peak height. This value, normally provided by the manufacturer is accepted. Using a mercury vapor lamp one can also check the spectral width. A number of well defined emission lines at 243.7, 364.9, 404.5, 435.8, 546.1, 576.9, and 579 nm can be used to check spectral bandwidth. However, the accuracy of the absorbance measured is dependent on the ratio of spectral bandwidth to the normal bandwidth (NBW) of the absorbing species. Most active pharmaceutical compounds have a normal bandwidth of approximately 20 nm or greater. With a SBW/NBW ratio of 0.1 or

less, absorbance can be measured with an accuracy of 99.5% or greater.

Resolution

Spectral resolution is a measure of the separation between two adjacent wavelengths. The two adjacent peaks are said to be resolved when the minimum absorbance between the two peaks is 80% or lower of the maximum absorbance. Most double-beam spectrophotometers have resolution below 0.5, typically 0.1. However, many diode array and rapid scan spectrophotometric detectors have resolution between 1 and 2 nm.

Photometric Accuracy

Photometric accuracy is determined by comparing measured absorbance to a certified absorbance of accepted standards. Solutions of potassium dichromate are recommended for evaluation of photometric

accuracy. [See Raghavan and Joseph (1997) under Bibliography] details about these standards. However, instrumental noise, drift, and stray light influence both photometric accuracy and precision. A discussion of these follows.

Noise

Noise in UV–vis spectrophotometry refers to uncertainties caused in the measurement of the absorbance signal. Essentially, there are two sources of noise. One is dependent on the source intensity (Schott noise) and the other independent of it. The effect of noise in spectrophotometric measurement can be significantly reduced if the concentration of the analyte is adjusted such that measured absorbance is between 0.3 and 1.2 absorbance units. A significant source of noise in double-beam instruments arises when sample and reference cells are not positioned properly. Minor imperfections in the cells cause reflections and scattering losses, which vary as a result of variations in the exposure of cell windows to the beam of light.

Drift

Photometric accuracy is also affected by drift. Drift is caused by changes in lamp intensity between measurements. This effect is nullified by subtracting the background absorbance of the analyte at a reference wavelength in a nonabsorbing region of the spectra. This process of “internal referencing” improves accuracy considerably. If the drift varies as a function of wavelength, two reference wavelengths, one before and one after the wavelength of interest, but in nonabsorbing regions, are chosen. This drift is assumed to be linear, and the drift calculated by linear fit at the wavelength of interest is subtracted.

Stray light and slitwidth

The spectral bandwidth is directly proportional to the slit width. When the slit width is narrowed, the bandwidth is less and thus the spectral purity increases. However, as the slit width is reduced, the signal-to-noise ratio also decreases proportionately, causing poorer precision. A slit width of 2 nm is adequate for most bands. A slit width of 0.5–1 nm is preferable for sharp bands. In HPLC detectors, to maximize the sensitivity, the slit width is automatically kept at 5 nm unless a rapid scan is carried out. During rapid scan, the slit width is normally changed to 1 nm. Stray light is any radiation identified by the detector outside of the narrow band of the wavelength selected by the monochromator. Scattering and diffraction inside the monochromator introduce stray light. Stray light is usually expressed as a ratio (or percent) of stray

light into the sample compartment or into the detector housing. In the specification, stray light is given to be 0.015% at 220 and 340 nm. Many currently available double-beam instruments have very low stray light values. Stray light values below 0.1% gives absorbance measurement errors below 0.5%, when the absorbancies measured are approximately 0.5 AU. Stray light becomes significant for quantitative measurement if the measurement is below 220 nm or above 330 nm because the source intensity is low in these regions. Manufacturers typically give stray light data at 220 and 340 nm. Stray light contributions increase with the age of the instrument. Therefore, the extent of stray light contribution needs to be assessed when necessary.

Factors that Influence Spectra

The position and intensity of the different bands in a spectrum depends on a number of factors. The effects of some of these may be considerable.

Solvent effects

The position and intensity of the different bands in a spectrum depend on the nature and conditions of the solvent used. In addition to electronic excitation, which causes absorption, vibrational and rotational energy level changes occur when light is absorbed. As a result, when spectrum is generated in the vapor phase vibration and rotation, fine structure is observable. However, in a solvent medium, because of thermal agitation and different types of interaction of the solute with the solvent, the position of λ_{max} may differ from solvent to solvent. In general, in polar solvents, interaction degrades the spectrum into broad bands because of molecular, electronic, and hydrogen-bond interactions. In aqueous solution, pH, concentration of analyte, ionic strength, and temperature can alter the position and intensity of maxima observed.

Deviation from Beer's law: Instrumental factor

The radiation entering a sample cell is a narrow band of polychromatic radiation. Thus, the effective molar absorptivity is an average of multiple wavelengths. As a result, the positive deviations from Beer's law may occur at low concentrations, whereas negative deviations may occur at higher wavelengths. Nonlinear behavior may also occur as a result of varying path length. When radiant beam is reflected at the solution/wall interface back into the solution, the beam traverses multiple paths. Thus, the net effective path length is increased and, therefore, the absorbance increases. This becomes pronounced (~0.3%) at low concentrations.

APPLICATION OF SPECTROPHOTOMETRIC MEASUREMENTS

In pharmaceutical analysis, spectrophotometric measurements are normally used for quantitative determination of known constituents. They are also used for qualitative analysis of compounds. These are addressed briefly. [See Gilpin and Pachla (1997, 1999) for extensive review of these methods.]

Qualitative Analysis

UV–vis spectrum of an analyte in solution is usually broad with very few narrow bands and shoulder. However, based on the nature of specific functional groups present in a molecule, some general spectral behavior was observed. Based on these studies and with the aid of quantum mechanical calculations, empirical relationships between structure and functional groups have been established. The terms commonly used in defining spectra are shown in Table 6.

Organic Functional Groups and Structure Elucidation

In a molecule, the absorption of ultraviolet or visible light represents the excitation of bonding electrons. Therefore, from the position of λ_{\max} and also from the intensity, the structure of functional groups present can be inferred. UV–vis spectroscopy can be used as a powerful tool to supplement identification of functional groups by other techniques. The electrons present in the ground state (lower energy state) of a molecule are excited to higher energy states by the absorption of light energy. This energy that is absorbed is measured. Some typical chromaphoric groups and their spectral characteristics are presented in Table 7.

The presence of an absorption band at a particular wavelength is a strong indication that a particular chromophore is present in the molecule. When additional functional groups are added, the characteristics change. For example, C–C double bond in butadiene absorb approximately at 214 nm. When a third double bond is conjugated, the absorption maximum is shifted to a longer wavelength by 30 nm. Also, alkyl substitution at a carbon atom leading to branching increases by another 5 nm. Empirical relationships, known as Woodward–Feiser rules, help predict the position of λ_{\max} in organic molecules. These empirical rules are applied to assign structures of organic molecules or distinguish between some isomeric compounds. Organic chemists use spectral data as an additional powerful tool to assign structures of organic compounds. [For a review of structure/spectra relationships, see Thomas (1997) in Bibliography.]

Spectra of Inorganic Ions

In the case of inorganic anions, generally excitation from a nonbonding lower energy state to an excited state (n to π^* transitions) is observed. For example, NO_3^- shows absorption at 313 nm. Chromate and dichromate ions have well-defined spectral absorption, which is used in calibration. However, from such data, conformation of identity is not possible. Inorganic cationic species, which are colored, usually exhibit very characteristic spectrum. These compounds with very well-defined absorption spectra are transition and inner transition metal cation coordination complexes. For example, a solution of copper is pale blue in aqueous slightly acidic medium, whereas in ammoniacal medium it is strong blue. These are attributed to splitting of “d” orbitals in the presence of ligands that complexes with the metal ion: one set of three d orbitals is called t_{2g} and the other set is known as e_g orbitals.

In aqueous solutions containing copper, the metal ion is octahedrally coordinated, i.e., the metal ion is at the center,

Table 6 Spectral characteristics of some organic functional groups

Species/functional groups	λ (nm)	ϵ ($\text{L mol}^{-1} \text{ cm}^{-1}$)
Satd. hydrocarbons	<200	—
Alkenes, alkynes, aromatic compounds, aromatic heterocyclic, highly conjugated aliphatics such as carotenes	200–500	$\sim 10^4$ – 10^5
Ethers, amines sulfides, alkyl halides	150–260	100–1000
Ketones, aldehydes, amides, esters, acids (—COOH), nitrates, <i>N</i> -heterocyclics such as pyridine	250–600	10–100

Table 7 Definition of spectral terms

Spectral term	Definitions and comments
Chromophore	A functional group, when present in a molecule, shows absorption in the region between 200 and 800 nm
Auxochrome	An additional functional group in the molecule, which causes shift to longer wavelengths
Hypsochromic (blue) shift	Shift of λ_{\max} to shorter wavelengths
Bathochromic (red shift)	Shift of λ_{\max} to longer wavelengths
Hyperchromic	Increase in intensity of absorption
Hypochromic	Decrease in intensity of absorption

and it is surrounded by six ligands, one at each apex of an octahedron. As a result of these coordinating ligands, the d orbital electrons, which are at the axis of the approaching ligand, experience forces of repulsion and attain higher energy state compared with those orbitals that are far removed from the axis of approach. The five equi-energetic d orbitals are split into two sets of equi-energy orbitals. The magnitude of the separation between the two energy states depends on the ligand field established by the ligands. In copper, of the nine d electrons, a set of six electrons occupy the lower energy state t_{2g} orbitals, and the other three occupy the excited state e_g orbitals. The e_g orbitals can accommodate four electrons. By absorbing visible light, an electron from the ground state can be promoted to the vacant excited state e_g orbital. This results in the characteristic absorption of many metals ions. EDTA, which is used in many pharmaceutical preparations, forms a hexa-coordinated complex, thus stabilizing and solubilizing metals. The example cited is for octahedral splitting. Similarly, in a tetrahedral field, the ligands can occupy the apex of a tetrahedron, and in a square planar complex, the corners of square plane. The tetrahedral and square planar complexes give rise to similar but different splitting of the d orbitals. Depending on which of these different ligand fields are formed different spectral patterns are observable for the same metal ion.

Charge Transfer Complexes

A third type of electronic transition that causes light absorption in the visible region is attributed to the formation of charge-transfer complexes. One example is the formation of the color blue by I_3^- when starch is used as an indicator in iodimetric titrations. A second example is the reaction between Fe^{3+} and thiocyanate ion SCN^- . In this case, an electron is transferred from a donor (SCN^-) to the acceptor (Fe^{3+}). The net effect is an internal redox reaction-forming Fe^{2+} and SCN radical. This type of internal redox reaction is generally reversible. However,

occasionally such charge transfer complexes may undergo irreversible redox reactions resulting in photochemical oxidation and reduction reactions. The formation of similar charge-transfer complexes in organic molecules results in the characteristic absorption in the UV region that can be used for qualitative analysis.

Qualitative Identification

The direct measurement of UV–vis spectra is rarely used for confirmation of identity of a component. However, the comparison of analyte spectrum obtained on a chromatographically separated component to that of a reference compound under identical chromatographic conditions is extensively used for identification and chromatographic purity of the eluting peak. Diode array/rapid scan spectrophotometers are very commonly used for this purpose. A perfect point-to-point comparison of spectra of two or more compounds is possible with the use of the proper computer algorithm. Under chromatographic conditions, the approach is to first establish that a particular drug or chemical substantially contains a single chromatographic component. Spectral data generated are then used for identity and for establishing the chromatographic purity of the analyte of interest. A second approach is to deduce identity by comparing the ratio of absorbance at peak maximum versus absorbance at peak minimum. *USP* 24 specifies such an identification procedure for cisplatin and methyldopate. For cisplatin, an absorbance ratio of 4.5 ($\lambda_{301}/\lambda_{246}$) is specified. However, in methyldopate hydrochloride, absorbance difference between a reference standard and the bulk drug at the same concentration should not differ by more than 3.0%.

Quantitative Analysis

Absorption spectroscopy finds extensive use in every field in which the quantitation of chemical component is

required. The characteristics of the spectrophotometric methods include the following:

- extensive applicability to a large number of systems;
- very high sensitivity (ppm to ppb levels can be determined);
- by the choice of wavelength, solvent, pH conditions, and added reagents, selectivity, which is normally poor, can be assured;
- excellent accuracy. Relative uncertainties of 0.5–3.0% can be easily obtained (under certain conditions, with appropriate precautions, errors can be minimized to 0.1%);
- very easy and convenient; and
- on-site data acquisition with certain type of probe spectrophotometers using hand held (palm) computers.

Application to Naturally Absorbing Species

Virtually all organic and many inorganic compounds absorb in the region between 210 and 700 nm. The conventional methods generally involve the following steps.

Selection of solvents

Any solvent exhibiting solubility of a few 10ths of a milligram to milligrams per milliliter is adequate for the purpose. Choice of the solvent is important such that it is transparent, i.e., background absorbance is extremely small. Organic solvents of spectrophotometric quality that is guaranteed to very small background absorbance are commercially available. Only these solvents are recommended for use. For aqueous solutions, the common variables such as pH, temperature, ionic strength of the medium, and the presence of interferants should be adequately controlled.

Selection of wavelength

Usually, from a spectral scan, the wavelength corresponding to the absorption maximum is selected. At λ_{\max} , sensitivity is maximum and, over a narrow region close to the maximum, the absorbance is constant. Therefore, minor wavelength differences do not alter the response, and also the absorbance at λ_{\max} is less sensitive to instrumental uncertainties. However, if adequate sensitivity exists, measurements can be made at λ_{\min} , if interfering absorbance is negligible at λ_{\min} .

Both reference and sample cells should be matched, properly cleaned, and rinsed before use. To eliminate lint and films from the outer surface of the cells, swipe cleaning with a lens paper soaked in methanol or

acetonitrile is recommended. When all these conditions are met and precautions are observed, quantitation is facilitated by comparison measurement. The reference standard concentration (C_s) is adjusted very close to the expected analyte concentration (C_u). Then standard (A_s) and sample (A_u) absorbencies are measured: $(A_u/A_s) \times C_s = C_u$.

This direct measurement can be used routinely for in-process assay of pharmaceutical formulations. The formulations during in-process conditions are not likely to contain potential degradants and thus, normally, the degradant interference is absent. Sometimes interference can be eliminated by solvent extraction of the impurities or of the analyte itself. Use of suitable nonabsorbing additives, which selectively reacts or masks the interference, can eliminate interference.

Method of standard additions

The method of standard additions may take one of several forms. If the matrix interference is constant and small, the sample is diluted to a known volume and the absorbance is measured. Then multiple volumes of a reference standard of the analyte at a known concentration are added and diluted to the same volume. The absorbance of each of the sample thus prepared is measured. From a plot of volume added versus absorbance and by extrapolation to zero volume of addition, the concentration of the analyte can be determined. Fig. 4 shows a plot of calculated absolute weight of a drug added to a fixed volume of solution as a function of measured absorbance. The x coordinate value of 4.08 corresponding to zero absorbance indicates the weight of drug in the sample.

Analysis of mixtures

The total absorbance of a solution is the sum of absorbance of the individual components in a mixture. For example, for a 1-cm cell, the total absorbances

Fig. 4 Plot of weight added versus absorbance.

measured at each of two wavelengths are related to concentration as follows:

$$A_{\lambda 1} = A_1 + A_2 = \varepsilon_1 c_1 + \varepsilon_2 c_2$$

$$A_{\lambda 2} = A'_1 + A'_2 = \varepsilon'_1 c_1 + \varepsilon'_2 c_2$$

Then a known concentration of each analyte is prepared. The absorbance of these solutions are measured at each of the two wavelengths. Solving the two simultaneous equations, two equations for c_1 and c_2 are obtained. Then the known values of individual concentrations and calculated values of the four molar extinction coefficients are substituted in the derived equations to arrive at the unknown concentrations of the two components in the mixture. Multicomponent analysis is normally used in the dissolution testing of tablets. Standard hardware and software components for multicomponent dissolution testing based on compendial method are available from instrument manufacturers.

Derivative Spectroscopy

The UV–vis spectrum is a display of absorbance as a function of wavelength $A = f(\lambda)$. At the absorbance maximum, the derivative $dA/d\lambda = 0$; the second-order derivative $d^2A/d\lambda^2$ is a negative maximum. For all even-order derivatives, the spectra show well-defined peaks, and these can be used for analyte determination. The advantages of derivative spectroscopy are as follows.

- Positions of local maximum are precisely defined in the derivative plot compared with the diffuse absorption maximum. As a result, distinguishable derivative spectra are obtained for different compounds, even though normal spectra are likely to be very similar.
- Overlapping spectra, which could not be resolved by conventional techniques, are easily resolved.
- In quantitative analysis, selectivity and sensitivity are increased.
- Combined with algebraic calculations, derivative spectroscopy can be easily adopted for multicomponent analysis.

Difference Spectrophotometry

This technique uses information obtained as the difference of two absorbance measurements when two components having very close λ_{\max} values are present in a sample or when there is matrix interference in the sample, the sample at the same concentration is introduced into the reference and sample cells. Then, composition of one of the cells is

modified by changing pH, or by adding a suitable reactant or by changing the temperature of the solutions. The difference in the absorbance is measured. For example, at pH 3.0, a particular species absorbs, and its absorbance is measured. By changing the pH to 7.0, the absorbance changes at the same wavelength. However, the contribution to absorbance of the interference remains the same regardless of pH. Then the difference between the absorbances measured cancels the absorbance owing to the matrix. This difference ΔA is proportional to the concentration.

In turbid or cloudy solutions, in which absorbance is affected by scattering of the sample, two absorbance measurements are made: one at λ_{\max} and the other at a different wavelength where the analyte does not absorb. Then, the difference being proportional to concentration of the analyte, the analyte concentration can be calculated. Difference spectrophotometry is used in the determination of constituents in tablets, complex pharmaceutical preparations, plant extracts, syrups, biological matrices such as blood and serum, injectable oil preparations, and the like. For this technique, in addition to other general requirements such as well-matched cells that are positioned accurately, the solution should be made homogeneous, and the instrumental stray radiation at the wavelength of interest should be extremely small.

Application to Nonabsorbing Species

The limitations of naturally absorbing species for the determination of analyte concentration more often suffer from poor selectivity, sensitivity, and interference in mixtures of components. In such cases, the target analyte is reacted with a suitable reagent that results in a product, that usually absorb at longer wavelengths either in the UV or, more often, in the visible region. An appropriate reagent is selected to meet one or more of the following needs:

- to quantitate spectrophotometrically inactive compounds. These compounds usually have active functional groups such as hydroxy group, amino groups, and the like, which react to yield spectrally active products.
- to increase selectivity. When multiple components, each of which has absorbance in the wavelength maximum of the analyte are present, suitable chemical reaction selective to the analyte, is selected so the effect of the absorbing components is eliminated.
- to increase sensitivity. In many cases, the analyte may have natural absorption. However, that may not be adequate to determine at a required level (ppb or ppm

levels). In pharmaceutical manufacturing, it may be necessary to establish that the active analyte has been cleaned of the manufacturing systems below a certain level. In these cases, sensitivity enhancements are possible using an appropriate chemical reaction to yield a product with high molar absorptivity. For example, in cisplatin, although it has good absorbance sensitivity at approximately 210 nm, the sensitivity is good only for few tenths of milligrams per milliliter of cisplatin and not adequate for trace-level determination. However, by reacting cisplatin with diethyldithiocarbamate (DDTC), platinum DDTC complex with high molar extinction coefficient is obtained. Increasing the concentration using a column-switching technique and chromatographic separation, a detection limit of 0.2 ppb was attained. [See Raghavan and Mulligan (2000) and Raghavan et al. (2000).] It is not always necessary to add chemical reagents. An oxidation product may be generated on electrochemical oxidation of an analyte or by using pulsed photochemical activation, species thus generated may be more spectrally amenable for quantitation. However, if reagents are chosen for reaction, the following need to be considered for successful sensitivity and/or selectivity optimization:

- appropriate reagent concentration, solvent, and composition of the mixture; ionic strength, pH, and temperature of the reaction mixture;
- adequate reaction time for completion or for reproducible response that is proportional to the concentration of the analyte; and
- similar treatment of reagent blanks to allow for matrix changes that might affect the reaction.

Excellent reviews of application of spectrophotometric methods based on chemical reactions are available in the literature (see Bibliography).

Measurement of Color

Color comparison tubes

In pharmaceutical formulations, pale yellow color may be imparted by the excipients or as a result of formation of colored degradants, or feebly colored products may be generated intentionally as in limit tests for heavy metals. In such cases for visual testing glass color comparison tubes, Nessler tubes, of uniform cross-section and flat bottoms are used. These tubes should be matched as closely as possible in internal diameter and length. The tubes are viewed downward through the solutions against a white background. The color intensity of the unknown is

compared with two successive standards, one above and one below the level of the unknown. The color is reported to be less than the most intense color standard with which it is compared. To meet compendial color requirements, special instruments are commercially available.

Probe-Type Spectrophotometers

Many dip-type UV–vis spectrophotometers, use fiber optic sampling technology coupled with highly sensitive charge coupled device (CCD) array detectors. The probe is immersed directly in the sample being measured. Then radiation from a light source is transmitted through an optic fiber to the tip. The light travels through the 0.5 cm through the sample and reflects off the back surface of curved mirror over another 0.5 cm through the sample and then back to an input filter. The sample absorbs part of the light and reflects back a small portion of the light that carries the spectral information of the sample. This reflected light travels back through suitably oriented fibers back to CCD array detectors. The spectrum is displayed through the use of the appropriate device. Direct measurement of concentrated solutions is made possible by amplifying the weak reflected light. As a result, this lends itself to on-line monitoring. Many remote filter optic sampling options for measurements not only on liquids but also on powder and solid objects are available. These spectrophotometers are miniaturized so that they can be hand-held and transportable for on-site measurements. Probe-type spectrophotometers are also useful for spectrophotometric titrations.

Spectrophotometric Titrations

The absorbance of a selected species is monitored as a function of volume of titrant added. The resulting absorbance data are plotted against volume of titrant. These titration curves have different shapes, depending on the absorbance characteristic of the analyte, added reagent, or the product formed. However, in all cases, the slope changes gradually near the equivalence point. Extrapolation of the two linear sections before and after the titration equivalence point yields an intersection point. The titrant volume corresponding to this intersection point is the equivalence point of the titration. Of the analyte, reagent added, or product in the solution, any one or two of these can be spectrally active. Therefore, a total of six possible titrant shapes are possible. Because the titration represents a series of analytical measurements, analytical accuracy is very high.

A variation of these titrations is used to determine stoichiometry and formation constant(s) of complexes. In these methods, typically the metal concentration and total volume of solutions are kept constant, but the ligand-to-metal ion ratio is continuously varied. From a plot of absorbance versus mole fraction, the stoichiometry between the metal and ligand can be obtained. Numerous variations of this method are adopted to obtain stoichiometry and formation constants or binding constants in many biochemical determinations.

VALIDATION OF SPECTROPHOTOMETRIC METHODS

The UV-vis spectrophotometric methods require validation of the method for the analysis of pharmaceutical compounds. Once the method is developed, data regarding precision, accuracy, linear response behavior, limit of quantitation, limit of detection, selectivity, and ruggedness are generated. These terms are very well-defined in many compendial monographs and in ICH, USP, and FDA guidelines. These are not addressed further. However, it should be emphasized that without appropriate validation data and reasonable understanding of how the method results will be affected by minor day-to-day variation of experimental parameters, routine generation of acceptable data may be difficult.

INTRODUCTION

Starch is one of the most commonly used excipients in the pharmaceutical industry due to its disintegration and binding properties. A number of sources of starch are commercially available, with corn starch being the most common. An overview of starches and starch derivatives and their use in the pharmaceutical industry is presented.

DESCRIPTION

Molecular Structure

Starch is a polymeric material with a molecular formula of $(C_6H_{10}O_5)_n$, where n ranges from 300 to 1000. Common starches contain two types of D-glucopyranose polymers called *amylose* and *amylopectin*. Amylose is a linear polymer of α -D-glucopyranosyl units linked $(1 \rightarrow 4)$ as shown in Fig. 1a. These molecules can be comprised of 100 to over 1000 glucose units. Amylopectin is a branched polymer of α -D-glucopyranosyl units containing $(1 \rightarrow 4)$ linear linkages and $(1 \rightarrow 6)$ linkages at the branch points, as shown in Fig. 1b. This polymer is three or more times larger than amylose. Most naturally occurring starches contain approximately 30% amylose, however, specific starches and their properties are determined by the size and amount of each type of polymer molecule present in the material. Attractive forces between the polymeric molecules form the starch granules. The linear portions tend to associate into micelles, which bind the molecules together to form a somewhat ordered structure. Models of this structure have been proposed (1), and it is known that the structure is rigid and insoluble in water.

Types of Starch

Starch can be derived from a number of natural sources, including those listed in Table 1 (2). It is found in various parts of the plants and several extraction methods are used to isolate the material. The most common type of starch used in the pharmaceutical industry is corn, although studies with other types of starch have been performed (3–6).

The most common preparation of starch is wet milling, although dry milling is also performed. A series of milling, separation, concentration, and washing steps result in a suspension of starch granules (7). After processing, cornstarch is a white powder with a pale yellow tint. Bleaching is required to achieve absolute whiteness.

A number of starch modifications are used in pharmaceutical applications. Pregelatinized or compressible starch has been chemically or mechanically processed to rupture all or part of the granules in water. It is then dried to yield an excipient material suitable for direct-compression formulations. Sterilizable maize starch contains magnesium oxide (not greater than 2.2%) and has been chemically or physically treated to prevent gelatinization on exposure to moisture or steam sterilization. Soluble starch results when potato or maize starch has been chemically treated to destroy the gelatinizing ability of starch.

General Properties

Starch is a fine white powder that is odorless and tasteless. It is composed of very small spherical or elliptical granules. The botanical origin of the starch material determines the granule shape and size, and these characteristics are summarized in Table 1. It is insoluble in alcohol, most solvents, and cold water. Alkaline solutions, however, will degrade starch and its polysaccharide components. Starch

Fig. 1 (a) Linear amylose starch molecule. (b) Branched amylopectin starch molecule.

is relatively resistant to enzymes other than α-amylase and amylglucosidase.

When starch is suspended in water and heated to a critical point called the gelatinization temperature, water will penetrate the granules and swell them to produce a viscous mass. With the rising temperature, the hydrogen bonds that hold the micellar structural units and the water molecules in an aggregated state tend to dissociate. The dissociated water molecules are then able to penetrate the weakened starch structure and gradually hydrate the many hydroxyl groups along the length of the starch molecule. Gelatinization temperatures vary from starch to starch, but range from 60 to 75°C (2). Starch granules lose their characteristic shape as gelatinization proceeds.

The reaction of starch with iodine is a common identity test for starch. A dilute solution of iodine stains starches a blue to bluish red color. It is believed that the amylose portion complexes with iodine by forming a helix around it (7). This blue color has been used both as a qualitative and quantitative test for starch in various systems.

The National Formulary (8) contains numerous assays for starch including botanical characteristics, identification, microbial limits, pH, loss on drying (LOD), residue on ignition (ROI), iron, oxidizing substances, sulfur dioxide, and organic volatile impurities.

PHYSICAL PROPERTIES

Structural Information

Starch is a semicrystalline polymer. The linear amylose molecules are amorphous in nature, but the branched

^a(From Ref. 11.)^b(From Ref. 12.)

amylopectin portion has been reported as partially crystalline. It is believed that the crystalline regions in the starch granule are interspersed in a continuous amorphous phase (1, 9, 10).

X-ray diffraction studies have shown that starch exists in three crystal forms designated as A, B, and C (10). These forms are dependent on the botanical source of the starch. Pattern A is observed for cereal grain starches, whereas pattern B is characteristic of tuber, fruit, and stem starches. Pattern C is intermediate between the A and B patterns and has been attributed to mixtures of A and B type crystallites. The A type pattern is commonly observed for cornstarch.

Single crystal X-ray diffraction data for the crystalline portion of A type starch have been reported and the crystallographic data are summarized in Table 2 (11). The unit cell contains 12 glucose residues located in two left-handed, parallel-stranded double helices packed in a parallel fashion. Four water molecules are located between these helices. It has been reported that the B type starch also contains chains arranged in double helices (12). The currently accepted hexagonal unit cell dimensions are in Table 2. The A and B structures differ in crystal packing of the chains and in moisture content.

Diffuse reflectance (DR) infrared (IR), Raman, and solid-state ¹³C cross polarization/magic angle spinning (CP/MAS) nuclear magnetic resonance (NMR) spectra were acquired for unmodified and pregelatinized cornstarch (13, 14). Differences were not evident in the spectra for the various starch samples. Solution-phase, ¹H-NMR studies have also been performed on amylose and model compounds (15). Spectral assignments and intramolecular hydrogen bonding suggest that the same conformation is perpetuated along the amylose chain.

Thermal Properties

Thermal analysis has also been used to characterize the structure of starch. A melting endotherm due to the crystalline portions of starch has been investigated (16), but it is not clearly resolved in all samples due to the small amount of crystalline material present in the samples. This transition is also dependent on the sample preparation and moisture content of the material. Melting points of 168–210° C have been reported (16, 17).

The glass transition temperature (*T_g*) in starch, measured using differential scanning calorimetry (DSC), was found to be dependent on the moisture content of the preparation and covered a temperature range of 22–130°C (18). Gelatinization studies of starch using DSC showed that concentrated starch/water suspensions produced a well-defined endotherm under select conditions. The endotherm was integrated to obtain the heat of gelatinization for various starches (19).

Microscopy

A number of excellent reviews on the microscopy of starches have been published (2, 20–23). As summarized in Table 1, the granule shape and size is characteristic of the botanical origin and can be used to identify the materials. It has been reported that the floury granules, as found for potato and tapioca starches, tend to be larger and more regular in shape (round, elliptical, or oval). Horny starches, such as corn and rice, are usually

Fig. 2 Scanning electron micrograph of unmodified cornstarch granules (magnification 2700×).

Fig. 3 Scanning electron micrograph of pregelatinized starch (magnification 100 \times).

described as polygonal because of the angular sides of the granules caused by the close packing of the granules in the kernel. An example is given in Fig. 2 for unmodified cornstarch. Starches are found as individual granules, but aggregated materials are also observed and are attributed to the drying conditions. Extensive heat and moisture during drying will produce a slight gelatinization of the surface of the granule and cause the granules to adhere together to form the aggregates. Pregelatinized starch exhibits an entirely different morphology, as shown in Fig. 3. The particles are irregular and the starch granules

Fig. 4 Optical micrograph of unmodified cornstarch under crossed polarizers (magnification 400 \times).

are not evident as expected from the pregelatinization process.

When unmodified starch granules are observed using polarized light, two dark lines will form a cross or a V-shape (Fig. 4). The shape of the cross can be used to help identify the type of starch. One explanation for this feature suggests that the density and distribution of moisture throughout the granule are not uniform (2). As the granules dry, stresses are formed within the granule resulting in the bright regions observed under the polarized light. When the starch swells or is gelatinized, the cross is no longer visible with the polarizing microscope.

Micromeritic Properties

Micromeritic properties, such as particle size, surface area, density, and flow properties can affect the disintegration, handling, and tableting properties of starch materials. A number of methods for determining the particle size of various starches have been used. For bulk powder analysis, sieving is employed for large amounts of material. Another common method for particle size determination is optical microscopy because it gives a direct measurement of the individual particles (14, 24, 25). Laser light scattering analysis has also been utilized to measure the size of dry particles and suspensions (26). This analysis was found to be dependent on the model used to fit the data, and better reproducibility was obtained with samples suspended in liquid. Surface area measurements of starches have been obtained by air permeametry (27) or nitrogen adsorption (14). Relatively low surface areas ranging from approximately 0.1–0.5 m²/g have been reported.

Bulk powder characteristics are important in understanding the handling properties of an excipient or a granulated product. A classification system to evaluate the flow properties of powders has been introduced by Carr (28, 29). A flowable powder is defined as free-flowing and tends to flow steadily and consistently, whereas a floodable powder exhibits an unstable, discontinuous, and gushing type of flow. A number of studies have investigated the bulk powder properties of starch (14, 30) and granulations made with starch (31, 32). The starch materials were found to exhibit poor to borderline flow properties.

Hygroscopicity

Starch has been classified as a moderately hygroscopic material (33). Water sorption studies have been conducted using static methods (saturated salt solutions in closed chambers) (33–35) modified inverse frontal gas chromatography (36), and automated moisture balance systems

Fig. 5 Moisture isotherm for unmodified cornstarch.

(14). The isotherms are typically type II curves exhibiting hysteresis, as shown in Fig. 5. Hysteresis in starch samples has been attributed to intra- and intermolecular hydrogen bonding of water with the hydroxyl groups of the starch molecule (33, 37). The extent of hydration and swelling depends on the accessibility of the hydroxyl groups in the starch to the water, and it has been suggested that the amorphous regions are responsible for the reversible swelling of starch upon the adsorption of water (9, 37).

USES AND APPLICATIONS

Starch is widely used in the pharmaceutical industry because, among its other properties, it is readily available, inexpensive, white, and inert. Excipient compatibility studies of starch and various active drugs have been performed using thermal methods of analysis. As an example, starch has been found to be compatible with cephalexin (38) and acetylcysteine (39) using this method of excipient screening.

Starch is described as a tablet/capsule diluent, tablet disintegrant, and glidant. The function of starch can depend on how it is incorporated into the formulation. Starch will function as a disintegrant when it is added in the dry state prior to adding a lubricant. It may exhibit both binding and disintegrant properties when it is incorporated either as a paste or dry before granulation with other agents. It has been reported that starches deform mostly by plastic flow during compression, but this was found to be dependent on the particle size, size distribution, and particle shape (40).

Starch is used in many formulations for its disintegration properties. The most common explanation for the disintegration properties is the swelling of the starch

granules when exposed to water, and it has been proposed that amylose is the component responsible for the disintegration properties of starch due to swelling. A second mechanism suggests that the disintegrating action of starch in tablets is due to capillary action rather than swelling. A third proposed mechanism is based on the particle-particle repulsion forces between the tablet constituents when in contact with water and the hydrophilic nature of starch (41).

A number of new applications have been reported for the use of starch in formulations. A new linear, short-chain, high surface area starch product was prepared by gelatinization followed by enzymatic degradation for use in directly compressible controlled-release systems (6). The combination of ibuprofen-starch granulates and hydroxypropyl cellulose was used to produce controlled-release formulations of ibuprofen (42). Gelatinization and freeze-drying has been used to produce cold water-swelling starch as well as a matrix forming excipient in sustained release tablets (43). Grafted starch microcapsules are being investigated for the oral administration of vaccines to prevent degradation (44).

STARCH DERIVATIVES

Unmodified starch has proven to be an effective and inexpensive disintegrating agent, however, relatively high concentrations have been required and the flow properties have been poor. The major shortcoming of starch is that while it is effective at disintegrating tablets, it is less effective at disintegrating the granules from which the tablets are made. When other properties, such as rapid disintegration, were necessary, new materials called starch derivatives were investigated.

Starches undergo many reactions characteristic of alcohols because of the many hydroxyl groups present in the structure. Modification of the D-glucopyranosol units can occur by oxidation, esterification, etherification, or hydrolysis. The resulting starch derivatives are defined by a number of factors such as plant source, prior treatment (acid-catalyzed hydrolysis or dextrinization), amylose/amylopectin ratio or content, molecular weight distribution or degree of polymerization, type of derivative (ester, ether, oxidized), nature of the substituent group, and physical form (granular, pregelatinized) (9, 45).

The degree of substitution (DS) is a common method of characterizing starch derivatives and is a measure of the average number of hydroxyl groups on each D-glucopyranosyl unit. It is expressed as the moles of substituent per D-glucopyranosyl units, and the maximum DS is 3 since

Fig. 6 Sodium starch glycolate molecule.

three hydroxyl groups are available in the unit for substitution. Most commercially produced derivatives have a DS less than 0.2. Molar substitution is used when the substituent group reacts further with the reagent to form a polymeric substituent. It is defined as the level of substitution in terms of mole of monomeric units (in the polymeric substituent) per mole of D-glucopyranosyl unit and can be larger than 3.

Sodium Starch Glycolate

Sodium starch glycolate is the sodium salt of a poly- α -glucopyranose in which some of the hydroxyl groups are in the form of the carboxymethyl ether (Fig. 6). Starch is carboxymethylated by reacting it with sodium chloroacetate in an alkaline medium followed by neutralization with acid. Cross-linking is achieved by physical or chemical methods. The sodium starch glycolate commonly prepared from potato starch is marketed as *Explotab* and *Primojel*. It is used as a tablet and capsule disintegrant and exhibits superior disintegration properties when compared to various starches (27). Sodium starch glycolates prepared from numerous starch sources (potato, corn, wheat, rice, sago, tapioca, and enset) have exhibited variations in disintegration efficiency, which have been related to the DS, cross-linking, and purity of the materials (46, 47).

Commercial sodium starch glycolate is a white to off-white, odorless, tasteless powder. It is an amorphous material with a T_g ranging from 128 to 156°C depending on the moisture content of the sample (33). It is considered to be a hygroscopic material based on the moisture uptake observed above 50% RH. It should be stored in a closed container to prevent exposure to wide variations in humidity and temperature that may cause caking. The material is composed of oval or spherical granules in the range of 30–100 μm . Flow properties measured for this material show that it is a free flowing powder that produced formulations exhibiting excellent mechanical properties (30).

Maltodextrins

Maltodextrins are carbohydrate materials prepared by controlled acid or enzyme hydrolysis (depolymerization)

Fig. 7 Maltodextrin molecule.

of corn starch. The D-glucose units are linked primarily by α -(1-4) bonds but have branched segments linked by α -(1-6) bonds, as shown in Fig. 7. The physical properties of these materials are determined by the degree of starch hydrolysis, which is expressed as the dextrose equivalent (D.E.) value. The D.E. is defined as the amount of reducing sugars present, which is reported as grams of D-glucose per 100 g of dry substance. A high D.E. value represents a low degree of polymerization of the maltodextrins.

The maltodextrin solids are amorphous, white, or off-white powders or granules, which are nonsweet and odorless. The materials are processed by spray drying, fluidized bed agglomeration, and roller compaction to improve their handling properties. Maltodextrins are hygroscopic above 50% RH and need to be stored below this RH in tightly closed containers. The powders will begin to gel when the materials are stored above 75% RH. The hygroscopicity of maltodextrins will increase with an increase in the D.E. value.

Maltodextrins are used as a coating agent, tablet and capsule diluent, tablet binder, and viscosity-increasing agent. They have been evaluated as a direct compression tablet excipient and were found to exhibit similar compression properties to those of other direct compression excipients (48). Studies relating the degree of polymerization and compression properties show that tablet properties such as density and tensile strength could be correlated to the degree of polymerization and the moisture content of the maltodextrins (49). Matrix pellet formulations using microcrystalline wax, maltodextrin, and various binders were used for sustained release and immediate release formulations (50).

SUMMARY

Starches and starch derivatives are important in the formulation of pharmaceutical drug substances. Various starch sources, starch modifications, and starch derivatives provide a wide range of solids, which can be used in

pharmaceutical applications. The various properties exhibited by the materials can be exploited for specific uses during the formulation process.

STATISTICAL METHODS

Charles Bon

AAI International, Wilmington, North Carolina, U.S.A.

INTRODUCTION

Death and taxes, as the old adage goes, are the only certainties in life. Although this is an overstatement, it does emphasize the uncertain world in which the pharmaceutical scientist lives and works. Faced with "estimates" of product characteristics such as potency, content uniformity, impurity levels, and dissolution performance, the scientist must make important go/no-go decisions. These estimated values, as is true for most measured quantities, inherently vary from the true values on which correct decisions depend. Statistical methods provide tools that enable the pharmaceutical scientist to act decisively in an uncertain world. An understanding of basic statistical methods is important for all who work in the pharmaceutical field.

SOME BASIC CONCEPTS

In the developmental process for many drugs, the drug product is administered under controlled conditions to healthy, normal individuals or to the targeted patient population. This is done to characterize the rate and extent of absorption, the bioavailability, of the active drug contained in the product. The bioavailability is estimated from the measured concentrations of the drug that appear in serial blood specimens collected over a period of time after product administration. Basic statistical principles govern the behavior of the typical bioanalytical procedure used to measure these concentrations in the collected blood specimens.

The first step of a typical procedure might involve the transfer of 0.5 ml of the specimen into a screw-cap culture tube using a disposable serological pipette. Next, 100 μ l of internal standard, a chemical structurally similar to the drug of interest, is added. A small volume, 1.0 ml, of a buffer solution at an appropriate pH level is added to decrease the aqueous solubility of the drug and internal standard. After thorough mixing, 7 ml of diethyl ether is added to the tube, and it is capped and shaken to extract the drug and internal standard into the organic ether phase. The tube is centrifuged to obtain a clean separation of

the aqueous and the organic phases. A 5-ml portion of the organic phase is transferred to a clean culture tube and is evaporated to dryness under nitrogen. The residual of the extract is reconstituted in 100 μ l of mobile phase, an acetonitrile/methanol/buffer solution, and 10 μ l is injected onto a high-pressure liquid chromatograph (HPLC) equipped with a 3- μ , C8 column. The column effluent is monitored for ultraviolet absorbance at 280 nm, and the drug and internal standard peak area, or height, responses are determined. The drug-to-internal peak response ratio is calculated, and an estimate of the concentration of drug in each specimen is obtained through interpolation of the ratio on a calibration curve. The calibration curve is constructed from the peak response ratios of extracted calibrator specimens containing known amounts of the drug in interference-free blood.

There are several obvious sources where error can contribute to the uncertainty in the concentration estimate. If, for example, 1.0 ml of the specimen is mistakenly transferred instead of 0.5 ml, but the correct volume was used for preparing the calibrators, systematic error would have occurred. Systematic errors lead to a constant, predictable uncertainty in the estimate. To deal with a systematic error, we must recognize that it has occurred and then correct for the mistake that led to its occurrence. Statistical methods do not address systematic errors. If, however, the correct 0.5 ml-volume of specimen and 100- μ l volume of internal standard were used, we still would have errors affecting the concentration estimate. These errors would be random errors. Random errors are positive and negative deviations that inherently occur in any attempt to exactly measure a quantity, in our case, specific volumes of the specimen and internal standard. We might transfer 0.498 ml of a specimen owing to an unrecognized air bubble interfering with our reading of the meniscus in the transfer pipette. Or, perhaps, 0.502 ml is transferred because of some of the specimen adhering to the outside of the pipette. Statistical methods are our tools for dealing with uncertainty resulting from random error (chance).

After the transfer of the specimen and the addition of internal standard, the drug-to-internal ratio becomes a fixed quantity. Any additional random or systematic volume errors should not affect the concentration estimate. Upon injection of the reconstituted extract onto the HPLC,

however, random errors will occur that do affect the estimate. These are the result of chance deviations in the partitioning of the drug and internal standard between the mobile phase and the column. Random fluctuations in the UV detection system will also affect the concentration estimate. The influences of random errors are statistically additive. In our example, the random errors are independent of each other in that the occurrence, sign (positive or negative), and magnitude of each are unrelated to the occurrence, sign, and magnitude of the others. This is in contrast to correlated errors, which are related to each other in some predictable way.

Two important characteristics of any assay method are its accuracy and its reproducibility. Accuracy is how close an estimate is expected to be in relation to the true value for the specimen. Reproducibility relates to how repeated estimates of the same specimen vary about their average value. Both accuracy and reproducibility are usually defined for a given concentration and may differ between low and high specimen concentrations. In a good assay method, these differences should be inconsequential across the working range of the method.

The expected value of an estimate is the average of an infinite number of determinations of the estimate. These infinite determinations, taken as an aggregate, make up the population of estimates. A population does not have to be infinite in size. Some examples of finite populations are the potencies for all tablets in a given lot of a drug product or the sitting blood pressures of all patients who use a certain antihypertensive medication in the coming year. The mean (μ) of a population is a parameter of the population. The estimate of μ , obtained from a single concentration estimate for a specimen, varies from one determination to the next and is aptly referred to as a variable. If a variable conceptually takes on a continuum of values, as is the case for a concentration estimate, it is called a continuous variable. Variables that take on only certain discrete values, such as the number of tablets produced from 50 kg of active drug material, are referred to as discrete variables.

It is impossible to conduct an infinite number of extractions of a specimen to determine the accuracy of a method. As a result, we estimate the accuracy of an assay by performing a finite number of extractions (n) on the specimen. We report the accuracy as the mean ($\bar{x} = \sum x_i/n$, $i = 1, 2, \dots, n$) of the multiple determinations, expressed as a percent of the known concentration. The finite group of determinations is a sample from the population, and its mean is referred to as the sample mean. The sample mean is a statistic that estimates the population parameter μ . If we could obtain the means from an infinite number of same-size samples, regardless of their size, then the mean of these infinite sample means would equal μ . In statistical

terminology, we say that the sample mean is an unbiased estimator of the population mean. Unbiasedness is a desirable property for any statistic. Some statistics only become unbiased when sample sizes are large. These statistics are said to be asymptotically unbiased. Such statistics have their greatest utility when used with larger samples, such as those consisting of 20–30 determinations rather than smaller numbers such as 2–10.

Reproducibility, or precision, of a method relates to how individual estimates fluctuate around the average value. The magnitude of the fluctuation in the population is expressed by the parameter variance (σ^2). Variance is the average of the squared deviations about μ for all values x_i in the population: $\sum (x_i - \mu)^2/N$. An unbiased estimate of σ^2 is obtained from the deviation of each value (x_i) around the mean (\bar{x}) for a sample taken from the population: $s^2 = \sum (x_i - \bar{x})^2/(n - 1) = (\sum x_i^2 - (\sum x_i)^2/n)/(n - 1)$.

The form of the equation not involving \bar{x} is a convenient calculating formula that avoids rounding problems that can occur when individual values are very close to the mean. It is common practice to report the standard deviation s , which is the square root of the sample variance. The standard deviation is often normalized as the percent coefficient of variation CV% by dividing it by the sample mean and expressing the result as a percent. In the analyses of pharmaceutical dosage units and in FDA regulations governing these analyses, the term relative standard deviation (RSD) is used for this calculated quantity instead of the term CV%.

Given two estimates of a statistic, one from a sample of size n and the other from a sample of size $2n$, one might expect that the estimate from the larger sample would be more reliable than that from the smaller sample. This is, in fact, supported by statistical theory. If the variance in the population is σ^2 , then the variance of the sample mean for samples of size n is σ^2/n . The square root of this is the standard error of the mean. Consistent with the variance of the sample mean being $1/n$ times that of a single determination (σ^2), the standard deviation and the CV% of the sample mean are reduced by the square root of n . As a direct consequence, an assay method that relies on the mean of two independent concentration determinations has a CV $1/\sqrt{2}$ that of the same method based on a single determination. This provides an easy way to increase the precision (reduce variability) of a method. An example of this is found in radioimmunoassay in which it is common for a concentration estimate to be calculated from the mean response of two determinations of a specimen.

As noted previously, fluctuations in concentration estimates about the true value arise from multiple, independent, random errors. Each of the independent errors (σ_i^2) is statistically additive, such that the total assay error

$\sigma^2 = \Sigma \sigma_i^2$. Similarly, the CV% of the assay will be the square root of the sum of the squared CV% values for all independent sources of error in the method. It is interesting to examine the impact of this on the determination of the important pharmacokinetic measure C_{\max} , the maximum concentration of a drug after administration of a drug product. For many drugs, the biological variability, the degree to which the true C_{\max} value varies during replicate administrations of the product to the same individual, can have a CV of 25% or greater. If an assay method has a 10% CV and the biological variability for C_{\max} is 25%, then the C_{\max} estimate would have a CV of 26.9%. This is simply the square root of the sum of the two squared independent error CVs: $25^2 + 10^2$. If the precision of the assay method was improved to 5% CV, C_{\max} would be estimated with a 25.5% CV. The effort required to reduce a 10% CV assay to half that level, to obtain a mere 1.4% increase in overall precision would seldom prove to be cost-effective.

A USEFUL STATISTICAL DISTRIBUTION

The normal distribution appears ubiquitously throughout science and nature. References to applications of normal theory are found throughout the pharmaceutical literature. The distribution is one of the earliest introduced, having been published in 1733 by De Moivre. Most scientists have a basic familiarity with the distribution and its characteristic bell-shaped curve (Fig. 1). Those familiar with column chromatography might recognize this shape as that of the perfect chromatographic peak. In fact, the

Fig. 1 The normal distribution.

principles of chromatographic peak symmetry and peak-to-peak resolution can be derived from normal theory. The normal distribution is defined by two parameters. The first, μ , defines the central location of the distribution, and the second, σ , defines the spread of the distribution about its center. The distribution has some unique properties. Its mean is the same as its median, the value at which 50% of the population are below and the remaining 50% are above. The distribution is symmetrical, its shape below its center is the mirror image of its shape above its center. Its mode, the value that occurs with the greatest frequency, also coincides with the mean and median. Approximately 68% of the distribution lies within 1σ of the mean, 95% lies within 2σ of the mean, and 99.8% lies within 3σ of the mean. The behavior of many observations in nature and many measurements in science can be approximated using the normal distribution. An important property that leads to the nearly universal application of the distribution is found in the central limit theorem. This theorem states that regardless of whether a given population is normally distributed, the distribution of the mean of randomly selected samples from the population will tend toward normality. This tendency increases as the size of the sample increases. If the population is, in reality, normally distributed, then a sample size of 1 is all that is needed. The more deviant the population distribution is from normality, the larger the sample size needs to be for its mean to be normally distributed.

It is reasonable to question whether the distribution of the estimates of a drug concentration in a blood specimen might be approximated by the normal distribution. Table 1 presents the results of repeated analyses of a specimen of interference-free plasma spiked to contain a known amount of drug. These data are taken from a comparative bioavailability study in which single doses of an unmarketed generic product and the marketed brand product of a drug were administered on separate occasions to healthy males. The values presented are the first of duplicate determinations of a quality control (QC) specimen that was included with each batch of subject specimens. This was done to verify that the in-process accuracy and precision of the assay method were consistent with the values observed during the assay validation.

A frequency histogram of the results is shown at the top of Fig. 2. The bottom of the figure shows the plot of the normal distribution with mean 207.6 ng/ml and σ 14.1 ng/ml. The shape of the histogram plot is similar to the plot of the normal distribution. The greatest deviation between the two is in the region of the center histogram. The sample distribution is higher peaked in its center, containing 42% of the values, than is the normal distribution, which has a 38% frequency at its center. The mean,

median, and mode of the QC values are close to being equal, as would be expected if the values had come from a normal distribution.

A particularly useful form of the normal distribution is obtained by transforming each value x_i to its standard normal value. This transformation converts the distribution to one that is independent of μ and σ . The conversion is $Z_i = (x_i - \mu)/\sigma$, where Z_i is known as the standard normal deviate and is normally distributed with $\mu = 0$ and $\sigma = 1$. Tables of Z -values can be found in any elementary statistics textbook. An example is presented in Table 2. The standard normal deviate table typically provides the proportion (area under the curve) of the distribution that lies between $-\infty$ and various Z -values (the lower tail) or between various Z -values and $+\infty$ (the upper tail). The proportion of the distribution lying within a given Z range around μ is calculated by taking the difference between the tabled proportions for $+Z$ and $-Z$.

Table 3 provides the expected percentages of the standard normal distribution that lie within some selected Z ranges about μ and compares these with the percentage of the QC sample distribution that falls within these ranges. The percentages for the sample distribution are

**Fig. 2** QC frequency histogram plot and corresponding normal distribution.

calculated by taking the number of QC values within each range, dividing it by 42, the total number of values in the sample, and expressing this as a percent. Because μ and σ are unknown, the sample mean and standard deviation are used in the calculations. The lower limit and upper limit values, in ng/ml, for each range is calculated as: $[x - Z \cdot s]$, $[x + Z \cdot s]$.

As seen in the frequency histogram, the observed distribution of the QC values in the vicinity of the mean, between $Z = -1$ and $Z = 1$, is higher than predicted by normal theory. However, the distribution outside this region closely resembles what would be expected for a normally distributed variable. A goodness-of-fit test to determine whether a variable follows a certain statistical

^aEnter Table by Z-value to obtain cumulative area entry. As an example, area for $Z = 1.96$ (entry at row 1.9, column 0.06) is 0.9750, indicating that 97.5% of the standard normal distribution is below this Z-value, and 2.5% is above. Areas for negative Z-values are calculated by subtracting the area for the positive Z-value from 1. For example, the area for $Z = -1.96$ is calculated as $1 - 0.9750$ or 0.0250.

^bTable values generated using the SAS System.

distribution can be constructed using a chi-square statistic (Table 4). The range of the sample values is divided into intervals, and the expected number of values (E) that should fall in each interval is calculated. It is important to keep the intervals large enough so that at least five observations are expected in each. The number of observed values (O) in the sample that falls within each interval is then determined. The chi-square statistic for this test is $\chi^2 = \sum[(O - E)^2/E]$. If the calculated statistic value

exceeds that of the critical upper tail, chi-square value at $\alpha = 0.05$ ($p = 0.05$ testing level), we reject the hypothesis that the sample distribution is consistent with the assumed statistical distribution. If our calculated value is less than the critical value, we accept the hypothesis.

The chi-square table (Table 5) is entered according to the significance level (e.g., $p = 0.05$) and the degrees of freedom (df) for the calculated statistic. The degrees of freedom for the goodness-of-fit test are the total number of

Table 3 Distribution of results of quality control specimen analyses

$\pm Z$ units about mean	Expected percent	Observed percent
3.0	99.7	100
2.5	99	98

0.7	52	64
0.5	38	55
0.2	18	24
0.1	8	12

intervals less one. If, as in our case, population parameters for the assumed statistical distribution are not known and must be estimated from the sample, then the degrees of freedom are further reduced by the number of parameters estimated. In our example using eight intervals and estimating the mean and variance of the normal distribution from the sample, there are $8 - 1 - 2 = 5$ degrees of freedom. The critical chi-square value at $\alpha = 0.05$ with 5 df is 9.24. As Table 4 shows, our calculated statistic value, 6.33, is less than the critical value. Accordingly, we accept the assumption that the QC values appear to come from the assumed normal distribution with $\mu = 207.6$ and $\sigma = 14.1$.

Normal distribution theory can be used to test whether a particular sample value is consistent with other values or with our past experience. If the mean μ and the variance σ^2 are known, then we can determine how deviant an observed value x_i appears to be by calculating the statistic $Z = (x_i - \mu)/\sigma$ and comparing this with the table of standard normal deviates. Suppose that one of the values for our QC specimen was 170 ng/ml. Past experience has led us to believe that the results for this QC specimen are normally distributed with $\mu = 207.6$ ng/ml and $\sigma = 14.1$. Is the value of 170 ng/ml consistent with the assumption (hypothesis) that the assay is functioning properly with only random errors operative. To test this, we calculate the Z-statistic, which is equal to $(170 - 207.6)/14.1 = -37.6/14.1 = -2.77$. From the table of standard normal deviates, we see that the proportion of the normal distribution that lies within the range $-\infty$ to -2.77 (or similarly, between 2.77 and $+\infty$) is 0.0028. Therefore, the probability of encountering a value this far removed from the mean (± 37.6 ng/ml) is $p = 2 \times 0.0028 = 0.0056$. Typically, when there is less than a 5% probability ($p < 0.05$) of observing a value, we would question

whether our hypothesis was correct. We conclude, therefore, that either we have just observed a relatively rare event or that the assay was not working as expected. The hypothesis that the observed value deviates from its expected value owing only to random fluctuation is called the null hypothesis. If the null hypothesis is rejected, then we accept some stated alternative hypothesis. In this example, the alternative hypothesis is that the assay method was not functioning properly.

The Z-test can also be used to test if the mean \bar{x} from a sample of size n is consistent with the known mean μ of the population. The Z-statistic for this test is equal to $(\bar{x} - \mu)/(\sigma/\sqrt{n})$, where σ/\sqrt{n} is the standard error of the mean. The statistic is evaluated against the table of standard normal deviates just as we did in determining whether the QC value of 170 ng/ml was acceptable.

It should be noted that although it is common to use the 5% level of significance ($p < 0.05$) for testing, this level is not always appropriate. If the rejection of the 170 ng/ml QC value causes us to evaluate if the conduct and performance of the assay for a particular batch of specimens were correct, then the 5% level is probably appropriate. At this level, we would expect to have to investigate the performance of 1 in 20 of the batch runs even when everything was functioning properly. This would result in what is statistically known as a Type I error. A 5% level of extra circumspection would generally not be a problem. However, if the rejection of the 170 ng/ml value led to our dropping the value from estimates of in-process accuracy and precision, then it is not generally acceptable to erroneously exclude 5% of the values, thereby calculating estimates on the best 95% of the results. In this case, a 1% level of significance ($p < 0.01$), or even lower, would be more appropriate. At this lower level of significance, we would reject fewer values that deviated from the expected value simply owing to random error. Although this appears to be desirable, testing at a lowered level of significance also reduces our ability to reject values that differ from expected owing to true assay performance problems. This nondetection of truly aberrant values is referred to as a Type II error. Generally, the only way to decrease both Type I and Type II errors is to increase the size of the sample used in the statistical test.

THE DISTRIBUTION OF THE SAMPLE MEAN

We seldom know the population variance and, therefore, must estimate it from a sample. If the population is normally distributed or if the sample is a large one from a

attributed to W.S. Gossett, who wrote under the pseudonym "Student," describes the behavior of the means for samples taken from a normal distribution. The t -distribution is defined entirely by the sample size n , or more typically by its degrees of freedom $n - 1$. The distribution has a shape similar to that of the standard normal distribution, bell-shaped, but for small samples is lower peaked and broader than the standard normal distribution. As the sample size increases, the distribution approaches that of the normal distribution, coinciding with it when the sample size is infinite. The t -statistic is used like the Z -statistic, for testing the consistency of a sample mean with the population mean μ . The difference between the two statistics is that for the t -statistic, σ is replaced by its sample estimate, the standard deviation s . The statistic is $t = (x \cdot - \mu)/(s/\sqrt{n})$. Table 5 provides a listing of critical t -values (think of them as t deviates) for different degrees of freedom ($n - 1$). Note that at infinite degrees of freedom, the critical t -value is simply the standard normal deviate Z .

Assume that the QC specimen was supposed to be prepared to contain 200 ng/ml of drug and that we do not know the true population variance. Is a sample mean equal to 207.6 ng/ml based on 42 determinations consistent with the true value being 200 ng/ml? This typically would be stated in the form of a null (H_0) and alternative hypothesis (H_a):

$$H_0 : \mu = 200 \text{ ng/ml}$$

$$H_a : \mu \neq 200 \text{ ng/ml}$$

Because σ for the population is unknown, we must estimate it from the sample standard deviation s . We calculate $t = (207.6 - 200)/(14.1/\sqrt{42}) = 3.49$. Referring to Table 5 and entering it with 40 degrees of freedom, the closest-value to the $42 - 1 = 41$ degrees of freedom for our calculated statistic, we find a critical, one-sided, t -value at

the 0.005 level equal to 2.70. If the calculated t -statistic value exceeds a tabled critical value ($t > t_{\text{crit}}$) or if it is less than the negation of the critical value ($t < -t_{\text{crit}}$), then the null hypothesis is rejected. In the example, the calculated value 3.49 exceeds the critical value and we reject the hypothesis that the sample comes from a population with a mean of 200 ng/ml at the 0.01 level of significance (2×0.005). We, instead, accept the alternative hypothesis that the QC specimen appears to have been prepared to contain a drug concentration different than 200 ng/ml. This is an example of a one-sample t -test.

Another application of the t -test is the two-sample t -test. This test is used to determine whether two samples come from populations with the same mean ($\mu_1 - \mu_2 = 0$) or whether the population means differ by some hypothesized amount ($\mu_1 - \mu_2 = c$). In both cases, the statistic is calculated as $t = [(x_1 - x_2) - (\mu_1 - \mu_2)]/se$, where x_1 and x_2 are the means of first sample and the second sample. The denominator of the statistic is the standard error for the difference between the two means, calculated as: $se = s_p(1/n_1 + 1/n_2)^{1/2}$, where, $s_p = [((n_1 - 1)s_1^2 + (n_2 - 1)s_2^2)/(n_1 + n_2 - 2)]^{1/2}$, s_1 and n_1 are the standard deviation and size of the first sample, and s_2 and n_2 are the standard deviation and size of the second sample. We enter the t -table with $n_1 + n_2 - 2$ degrees of freedom. If the tabled value is exceeded by our calculated value or if the calculated value is less than the negation of the tabled value, then we reject the hypothesis that the two samples are from populations with the same mean or differ by the hypothesized amount c .

Assume that we have a second set of 20 QC values from a second QC specimen, presumably prepared identically to the specimen from our previous set of values, and found a mean of 199.6 ng/ml and standard deviation 13.5 ng/ml. We can evaluate whether these results are consistent with those from 42 results on the first QC specimen. The null hypothesis for the test is that the two QC specimens have been prepared identically, $\mu_1 - \mu_2 = 0$. The alternative hypothesis would be that they are not identical, $\mu_1 - \mu_2 \neq 0$. The standard error is $se = [(41 \times 14.1^2 + 19 \times 13.5^2)/(41 + 19)]^{1/2}(1/42 + 1/20)^{1/2} = (193.566)^{1/2}(1/42 + 1/20)^{1/2} = 3.78$.

The t -statistic is $(207.6 - 199.6)/3.78 = 2.12$. Entering Table 5 with 60 degrees of freedom, we obtain a critical t -value for a one-sided test at the 0.025 level of significance equal to 2.00. As the alternative hypothesis is that the two QC specimens differ, without regard to which has the higher and which has the lower value, the test is a two-sided test. The critical table value at 0.025, one-sided, is the critical value to use for a two-sided test at 0.05. The calculated statistic exceeds this critical value, and we reject the hypothesis that the two sets of QC samples were

prepared identically. If we have the stock solutions used to prepare the two QC specimens, we would probably analyze them to see whether they have identical concentrations.

The t -distribution can also provide a tool to evaluate whether two samples on which paired determinations had been obtained appear to come from populations with the same mean (or from the same population). A paired t -test can be applied when we want to determine whether a newly trained analyst performs an assay method with the same proficiency as an experienced analyst. Suppose that each analyst processes seven different QC specimens and we obtain the following assay results, in the order (new analyst, experienced analyst): (12.6, 11.3), (3.46, 2.34), (25.4, 22.5), (10.3, 8.80), (5.89, 4.68), (16.4, 14.2), and (9.95, 8.20). The paired t -test deals with the differences for each of the paired results (new-experienced): 1.3, 1.12, 2.9, 1.5, 1.21, 2.2, and 1.75. The mean difference is 1.71, with a standard deviation of 0.641. The t -statistic is calculated by dividing this mean by the standard error (standard deviation/ \sqrt{n}) and comparing the result with the critical t -value with $n - 1$ degrees of freedom. With the $n = 7$ pairs in the example, the calculated t -statistic is $1.71/(0.641/\sqrt{7}) = 7.06$. This exceeds the critical t -value 2.45 for the two-sided, 0.05 level of significance (the one-sided 0.025 value in Table 5) with six degrees of freedom. We conclude that a difference as large as the one observed between the two analysts would not likely be attributable to random error alone. The "new" analyst may need some additional training.

ANOTHER USEFUL DISTRIBUTION

A commonly encountered statistical distribution is the binomial distribution. This distribution deals with the behavior of binary outcomes such as the flip of a coin (heads/tails), the gender of a child (boy/girl), or the determination if a tablet has acceptable potency (pass/fail). When dealing with a sequence of independent binary outcomes, such as multiple flips of a coin or determining whether the potencies of 20 tablets are individually acceptable, the binomial distribution can be used. The probability of observing x successes in n outcomes is $C(x,n) p^x q^{n-x}$. Binomial expansion for $x = 1$ to n is $C(0,n)p^0 q^n + C(1,n)p^1 q^{n-1} + C(2,n)p^2 q^{n-2} + \dots + C(n,n)p^n q^0$. This sum equals 1, as the probability of observing at least one of the possible outcomes is 1 (a certainty). The notation in the expansion $C(a,n)$ is the number of ways of obtaining groups of size a from n distinct items: $n!/a!(n-a)!$. As an example, the number of groups of size three obtainable when there are four

different items is $C(3,4) = 4!/[3!(4-3)!] = (4 \times 3 \times 2 \times 1)/[(3 \times 2 \times 1)(1)] = 4$. Note that $0!$ is defined as 1. The p in the binomial expansion is the success probability for the single binary event such as observing a head with one flip of a coin. The q stands for the single-event failure probability (e.g., observing a tail) and is equal to $1 - p$.

PUTTING IT ALL TOGETHER

In the analyses of blood specimens from subjects participating in bioavailability studies, the FDA instructs laboratories to include quality control specimens (QC) at each of three known concentrations (low, mid, and high). The QC specimens are processed in duplicate with each batch of subject specimens. The acceptance criteria for the batch, based on the results of these QC specimens, is that at least four of the six values must fall within a specified range about their nominal concentrations. In addition, no more than one value at each of the three QC concentration levels can be outside its acceptance range. Combining binomial and normal distribution theory, we can estimate the number of batch runs we expect to reject because of random error.

Assume that the acceptance limit for each QC value is that it must fall within 15% of its nominal concentration. Any value meeting this criterion passes and any not meeting this criterion fails (a binary outcome). The probability of accepting a batch run based on multiple binary outcomes (QC pass/fail determinations) will be governed by the binomial distribution. The probability of a single QC value failing is equal to the probability of obtaining a concentration outside 85–115% of its nominal concentration. The concentration estimates are assumed to be normally distributed with a mean equal to 100% of the nominal concentration. The sigma value for the estimates is equal to the CV of the assay. If the assay CV is 12%, the probability of a QC value passing acceptance criteria is the probability of obtaining a Z-value between $(85 - 100)/12$ and $(115 - 100)/12$ or between -1.25 and $+1.25$. The proportion of the standard normal distribution between -1.25 and $+1.25$ is 0.7888, which is p , the probability of a single QC value passing. The value of q is $1 - 0.7888$ or 0.2112. There are three mutually exclusive ways that at least four of the six QC values can pass the acceptance criterion. All six values could pass, five of the six could pass, or four of the six could pass. These outcomes are mutually exclusive; the occurrence of any one of them excludes the possibility that either of the other two occurs. The probability of at least four of six QC values passing, then, is the sum of the probabilities of each of the three mutually exclusive ways in which this event can occur.

It should be noted that in probability calculations, when an event A can occur through any one of the mutually exclusive events B, C, D, etc., then the probability of A is the sum of the individual probabilities of B, C, D, etc. However, if A occurs only when events B, C, D, etc. all occur, then the probability of A is the product of the individual probabilities of B, C, D, etc.

Applying the binomial expansion, the probability of at least four of the six QC values passing is $C(6,6)p^6q^0 + C(5,6)p^5q^1 + C(4,6)p^4q^2 = 1(0.7888)^6 + 6(0.7888)^5(0.2112) + 15(0.7888)^4(0.2112)^2$, which equals 0.8869. For a batch to pass, however, we have the additional restriction that when only four of six values pass, no more than one of the two failures can occur at the same QC level (low, mid, or high). This restriction reduces the 15 possible ways that four of six QC values can pass to 12. This reduces the probability of the batch being accepted to $0.8869 - 3(0.7888)^4(0.2112)^2$ or 0.8351. There is an 83.5% probability of accepting a batch run, and there is nearly a 16.5% chance of rejecting it because of random error. We might consider improving the precision of the assay rather than proceeding with a method that is anticipated to erroneously reject nearly 17% of our analyses. If the CV% of the method were improved to 8%, the probability of batch acceptance increases to 0.9875, and our expected failure rate is only 1.2%. With 42 batch runs, we expect to have to repeat 1–2 batches, as contrasted with the 12% CV assay, where we expect to repeat seven batches. Here is a case in which a modest improvement in assay precision reaps big rewards.

The chi-square distribution used in the goodness-of-fit test is useful in another important statistical test. Assume that previous experience leads us to believe that the σ of an assay method is no greater than 10 ng/ml. In processing 42 batches, the observed standard deviation was 14.1 ng/ml for the QC values. Is this result consistent with the prior knowledge of the assay ($H_0: \sigma \leq 10$), or does it appear that the precision of the assay has deteriorated ($H_a: \sigma > 10$)? Application of a chi-square test can help answer this question. The appropriate statistic in this case is $\chi^2 = (n - 1)s^2/\sigma^2$, which follows a chi-square distribution with $n - 1$ degrees of freedom. In our example, we replace s in the statistic with 14.1, our sample standard deviation, and σ with our assumed upper limit of 10 for σ . The calculated statistic for this one-sided test is $\chi^2 = (42 - 1)14.1^2/10^2 = 81.51$. This calculated value exceeds the critical chi-square value 59.34 at the 0.005 level of significance and 40 (approximately 41) degrees of freedom. We conclude that the assay precision had deteriorated and would probably launch an investigation as to why.

In manufacturing a drug product, it is common to collect and analyze specimens from the mix of active and inactive

ingredients, the blend. This is done to verify adequate uniformity of the blend before proceeding with the manufacturing process. The specimens are strategically collected from the blend container, for example, from the left, center, and right regions of the top, middle, and bottom of the container. Blend uniformity criteria usually require that the mean assay value for the specimens falls within an acceptable range (e.g., 95–105%) about the label claim (100% potency) for the product. In addition, the relative standard deviation CV% for the analyses of the blend specimens must not be greater than some specified limit (e.g., 5%). Using the characteristics of the normal and the chi-square distributions, we can estimate the chances of passing blend uniformity criteria.

Suppose that prior knowledge of the manufacturing process leads us to believe that we routinely produce blends with potencies between 97 and 103% of label claim. We estimate that the variability for a “good” blend is no more than 3% CV, a composite of true blend inhomogeneity, sampling error, and analytical method variability. What is the probability of accepting a good blend? The standard error of the mean for nine specimens from the blend will be 1%, our worst-case estimate of CV for a single determination (3%) divided by the square root of the number of specimens collected (9). Assuming that the true potency of the blend is 97% (a worst-case estimate), then the probability of observing a mean from nine blend specimens that is within our acceptance range of 95–105% is the same as the probability of observing a Z -value between $(95 - 97)/1$ and $(105 - 97)/1$ or between -2 and $+8$. The proportion of the standard normal distribution contained between -2 and $+8$ is 0.977, the probability of passing the first criterion for blend acceptance. The second criterion is that the CV of the nine blend specimens must be less than 5%. With a true CV of 3%, this is the probability of observing a chi-square value less than $(n - 1)5^2/3^2 = (8)(25)/9 = 22.2$. With eight degrees of freedom, the probability of a chi-square value less than 22.2 is approximately 0.996, which is the probability of passing the second criterion. The probability of accepting the blend material is the product of the individual probabilities of passing criterion 1 and criterion 2, or 0.977×0.996 , which equals 0.973. Therefore, 97% of our blend batches are expected to pass if only random error is operative.

Some have proposed widening the acceptance range (e.g., 90–110%) but requiring that all individual blend specimens fall within the widened range. Is this an easier or harder criterion to meet? The probability of a single-blend specimen being acceptable, is the probability of the standard normal deviate Z being between $(90 - 97)/3$ and $(110 - 97)/3$ or between -2.33 and $+4.33$. This probability is 0.99. For the blend to pass the first criterion,

the first specimen, the second, and the third, up through the ninth, must all, independently, be acceptable. The probability of passing this first criterion becomes 0.99^9 , or 0.914. This, when combined with the probability of meeting the second criterion, results in a probability of blend acceptance being 0.914×0.996 or 0.91. Only 91% of the blends are expected to pass. The chance failure rate goes from approximately 1 in 30, based on using the mean to 1 in 11 based on using individual values, despite the widened acceptance limits.

ONE FINAL DISTRIBUTION

There is one final statistical distribution, the F -distribution, that is an important addition to the basic statistical tool chest. This distribution is used in the evaluation of two variance estimates to determine whether they are consistent with each other. The QC sample based on 42 estimates (41 degrees of freedom) had a standard deviation of 14.1 ng/ml. If we had another set of 31 QC values (30 degrees of freedom), perhaps from a second bioavailability study, with a standard deviation of 19.5 ng/ml, we might want to know whether the assay precision values for the two studies were consistent. The variance ratio statistic is s_1^2/s_2^2 , where s_1 is the higher of the two standard deviations, and s_2 is the lower of the two. The calculated value of the statistic is compared with tables of critical F -values with $n_1 - 1$ numerator and $n_2 - 1$ denominator degrees of freedom. In our case, the critical $F_{30,41}$ is approximately equal to 1.74 at the 5% level of significance (see Table 6 for $F_{30,40}$, the closest value). The calculated ratio is $19.5^2/14.1^2 = 1.91$, which exceeds the critical value. The interpretation is that the assay precision for the second of the two studies differs significantly ($p < 0.05$) from that of the first (it has less precision, greater CV%).

The F -distribution has great utility in a statistical test referred to as analysis of variance (ANOVA). ANOVA is a powerful tool for testing the equivalence of means from samples obtained from normally distributed, or approximately normally distributed, populations. As an example, suppose that the following are the content uniformity values on 20 tablets from each of four different lots: lot A mean = 99.5%, standard deviation = 2.6%; lot B mean = 100.2%, standard deviation = 2.8%; lot C mean = 90.5%, standard deviation = 2.1%; and lot D mean = 100.3%, standard deviation = 2.7%.

Are any of the lots different from the other lots? To answer this question, we need to conduct a statistical test with a null hypothesis $H_0: \mu_1 = \mu_2 = \mu_3 = \mu_4 = \mu$

(all means are equal to some unknown μ), and an alternative hypothesis H_a : $\mu_1 \neq \mu$ or $\mu_2 \neq \mu$ or $\mu_3 \neq \mu$ or $\mu_4 \neq \mu$ (at least one mean is not equal to at least one of the other means). It is assumed that all lots have the same, unknown, variance, σ^2 . The F -statistic involves the calculation of two variance estimates $s_1^2 = 1/(k - 1) \sum n_j(x_{.j} - x_{..})^2$ and $s_2^2 = 1/(N - k) \sum \sum (x_{ij} - x_{.j})^2$. In the statistic, $x_{..}$ is the grand mean across all $k = 4$ lots, n_j is the number of values from which the j th lot mean $x_{.j}$ was determined (20 for each lot), and $N = \sum n_j = \sum \sum n_{ij}$ is the total number of x_{ij} values ($20 + 20 + 20 + 20 = 80$). The s_1^2 is a pooled variance estimate of how the category means vary about the grand mean, and s_2^2 is a pooled variance estimate of how the individual values within each category vary about their category mean. If the identification (grouping) of the values into categories (lots) does not affect the variance estimate, then the variance ratio s_1^2/s_2^2 will differ from 1.0 by only random error. The F -distribution describes how the ratio varies about 1.0 owing to random error when a set of values are arbitrarily grouped into categories. If the calculated statistic value exceeds the critical $F_{k-1, N-k}$ tabled value, then the null hypothesis of equal means is rejected.

In our example, $x_{..} = \sum n_j x_{.j} / N = (20 \times 99.5 + 20 \times 100.2 + 20 \times 90.5 + 20 \times 100.3) / 80 = 97.625$. $s_1^2 = (1/3)[(99.5 - 97.625)^2 + (100.2 - 97.625)^2 + (90.5 - 97.625)^2 + (100.3 - 97.625)^2] = 22.689$. Because the square of the standard deviation in each lot j is $s_j^2 = \sum (x_{ij} - x_{.j})^2 / (n_j - 1)$, we can calculate s_2^2 as $(1/(N - k)) \sum (n_j - 1) s_j^2 = 1/(80 - 4) [19 \times 2.6^2 + 19 \times 2.8^2 + 19 \times 2.1^2 + 19 \times 2.7^2] = 69.0$. The calculated variance ratio is $53.8/6.575 = 8.18$ and the critical 5% level $F_{3,76}$ is < 2.76 . The critical value 2.76 is that of $F_{3,60}$ in Table 6. This value is the closest tabled value with the desired numerator degrees of freedom (3) and denominator degrees of freedom 60, which do not exceed $N - k = 76$. As the calculated statistic value exceeds the critical F -value, we reject the null hypothesis that the means of all lots are the same. We accept the alternative hypothesis that at least one of the four means differs statistically from at least one of the other means. Looking at the four means, it appears that lot C differs from the others.

Instead of performing ANOVA, we might have considered pairing each lot mean with each of the other lot means and performing multiple two-sample t -tests to determine which ones differ significantly from the others. This approach would not be acceptable. First, it does not use all of the available information for the pooled denominator variance estimate. Second, it introduces what is known as the multiple comparison problem. The problem arises if there are multiple, separate, statistical evaluations conducted on the same set of data. When we

conduct a single test of a hypothesis at the 5% level of significance ($\alpha = 0.05$), such as $H_0: A = B$, we expect to falsely reject the hypothesis 5% of the time when A actually equals B (Type I error). We have, therefore, a 95% probability of being correct in the assessment when the null hypothesis $A = B$ is true. This is also true for the F -test of $A = B = C = D$ in ANOVA. If we were to independently perform multiple t -tests on our data with hypotheses such as $A = B$, $B = C$, $C = D$, $A = C$, etc., then for each of these 5% level tests, we have a 95% probability of obtaining a correct assessment when the null hypothesis that all means are equal is true. To correctly accept the null hypothesis of all means being equal, we must simultaneously conclude that $A = B$ and $B = C$ and $C = D$ and $A = C$, etc., from the multiple t -tests. The probability of doing so is $(0.95)(0.95)(0.95) \dots (0.95) = (0.95)^n$, where n is the number of pair-wise comparisons conducted by t -tests. The probability of being incorrect in this multiple pair-wise approach is $1 - (0.95)^n$, which exceeds the desired 5% level for any $n > 1$. In our case, there are $C(4, 2)$ or six possible pair-wise comparisons. The multiple pair-wise approach has a probability of an incorrect assessment, Type I error when the null hypothesis is true, equal to $1 - (0.95)^6 = 0.265$. This approach would essentially be testing at a 26.5% level of significance, rather than at the desired 5% level. For this reason, we only consider pair-wise examination of the data when the global assessment of equality of means is rejected by ANOVA. This maintains the desired 5% significance level.

For the post-ANOVA, pair-wise evaluations, there are procedures to deal with the multiple comparison problem. One such procedure is based on the F -distribution with one and $N - k$ degrees of freedom. This test also relies on the value of s_2^2 from ANOVA. The test statistic is $F = (1/s_2^2) [(x_{.1} - x_{.2})^2 / (1/n_1 + 1/n_2)]$, where $x_{.1}$, $x_{.2}$ are the means of the n_1 and n_2 values for the two lots in the pair-wise comparison. Comparing lot A and lot C: $F = (1/6.575) [(99.5 - 90.5)^2 / (1/20 + 1/20)] = 123.2$. This far exceeds the critical $F_{1,76}$ value at even a 1% level, which is < 7.08 , based on $F_{1,60}$, and we therefore reject the hypothesis that lot A and lot C means are equal. Because, the means for lot B and lot D differ from that of lot C by an even greater amount, they also are found to be statistically different from the lot C mean. By contrast, the comparison of lots A and D, with means of 99.5% and 100.3%, respectively, have an F -test value of 0.97, far less than the critical 5% value, which is < 4.00 .

The test of the four lots is an example of a one-way ANOVA. The one-way comes from the fact that there is only one category (lot) into which the data is classified. Often, we have more than one category (class variable) in which we need to classify data. Although our interest may

Table 6 Critical values of the *F*-distribution for 5% level of significance^a

^bTable values generated using the SAS System.

be to determine only whether a particular class variable has meaning, it is important to include other class variables that may influence the variability of the data. ANOVA involves a null hypothesis for each classification variable that proposes that the means at each different level of the class (category) are all equal. If we reject the null hypothesis we conclude in favor of the alternative hypothesis, that at least one mean in the class differs from at least one other mean in the class. This is also a conclusion that categorizing the data by that class variable has meaning.

Assume that we have two analysts to determine the drug concentrations in plasma specimens from a bioavailability study, using our previously described analytical method. Before starting the analyses, we want to determine whether they are equally proficient with the method. We might set up the test by obtaining plasma specimens at three different concentrations of drug. We then have each analyst process in duplicate each specimen on each of two different days. The resulting drug concentration values can be categorized by three different class variables: analyst, day, and specimen. The variable analyst has two possible levels, analysts one and two. Day has two levels (days 1 and 2), and specimen has three (A, B, and C). ANOVA on the results is a three-way one, named for the three classification variables included. Our interest is in the classification by analyst, but the other two variables are necessary to properly define how the experiment was conducted. Table 7 shows the results of the experiment.

ANOVA calculations are straightforward in this example and are easily expanded to situations in which there are higher numbers of categories. The first ANOVA quantity we calculate is C , the correction factor. C is simply the square of the sum of all the individual values, divided by N , the total number of values: $(\sum x_{ijkl})^2/N$, where $i = 1-2$ (analysts), $j = 1-2$ (days), $k = 1-3$ (specimens), and $l = 1-2$ values for each specimen for each analyst on each day. Table 8 demonstrates the calculation of this and the other calculated ANOVA quantities. The quantity A is calculated as the sum of the squared individual values: $\sum x_{ijkl}^2$. The ANOVA quantity for each classification variable (category) is the sum of the squared totals for each level of

Table 7 Evaluation of the proficiency of two analysts to process plasma samples

Specimen	Day	Analyst 1	Analyst 2
A	1	52.8	57.9
A	1	52.3	57.5
A	2	53.3	58.0
A	2	52.1	57.0
B	1	42.2	45.6
B	1	42.4	44.2
B	2	41.7	43.8
B	2	40.4	44.1
C	1	56.8	64.0
C	1	57.0	64.9
C	2	59.6	62.6
C	2	57.2	61.8

the classification, divided by the number of values in each level of the classification. As seen with the variable specimen, this is the sum of the squared totals for the values for each of the specimens A, B, and C, all divided by 8, the number of values for each specimen (2 values for each of 2 days for each of 2 analysts). The principle of ANOVA is that the total sum of squares SS_{Total} is divisible into its component sums of squares for each classification variable plus random error: $SS_{\text{Total}} = SS_{\text{Analyst}} + SS_{\text{Day}} + SS_{\text{Specimen}} + SS_{\text{Error}}$. The total sums of squares are calculated as the difference between two ANOVA quantities, $A - C$. The sums of squares for each classification variable is its ANOVA quantity minus C . The sums of squares for random error is determined by difference: $SS_{\text{Error}} = SS_{\text{Total}} - SS_{\text{Analyst}} - SS_{\text{Day}} - SS_{\text{Specimen}}$. The degrees of freedom are also additive with $df_{\text{Total}} = df_{\text{Analyst}} + df_{\text{Day}} + df_{\text{Specimen}} + df_{\text{Error}}$. The total degrees of freedom are simply the total number of values less one. The degrees of freedom for each class variable are the number of levels within the class less one. The error degrees of freedom are determined by difference. Dividing each sum of squares by its degrees of freedom provides the mean square MS , which is an estimate of the population variance σ^2 .

Table 8 Calculation of ANOVA quantities

	Totals	No. of observations	Σ (Totals squared)/No.
All 24 values	1269.2	24	$C = 67119.53$
Days 1 and 2	637.6, 631.6	12	$T = 67121.03$
Analysts 1 and 2	607.8, 661.4	12	$K = 67239.23$
Specimens A, B, and C	440.9, 344.4, 483.9	8	$R = 68395.42$
		Square of each value	$A = 68541.24$

Total	23	1421.7133 ($A - C$)		

^aIndicates statistical significance ($p < 0.05$).

Table 9 shows the construction of the ANOVA table. If the variance estimate of a class variable MS_{variable} deviates significantly from that obtained by that for random error MS_{Error} , then the null hypothesis that the means at the different levels for that variable are equal is rejected. In other words, the classification of data by that variable is explanatory of the variation observed in the data. We conduct the test by using the variance ratio test $F = MS_{\text{variable}}/MS_{\text{Error}}$, with numerator degrees of freedom equal to those of the variable and denominator degrees of freedom equal to that of the error term. As shown in Table 9, we reject the hypothesis that the two analysts process the specimens equivalently. We also see, as we expected, that the specimen levels *A*, *B*, and *C* are not equal. There are no detectable differences in the values obtained over the 2 days of processing.

In the previous example, we tested the hypothesis of “equality.” In reality, our interests are usually not in equality but in “comparability.” We generally do not require, or even logically expect, that two lots of the same pharmaceutical product will have the exact same potency. If we had several different lots of a drug product and analyzed enough units from each (e.g., 100–200 tablets), we could detect as statistically significant even a 1% difference in the potency between the lots. Although statistically significant, such a difference would have no practical significance. We require, however, that the potencies, as with the analysts’ performance on an assay, be comparable, allowing for a reasonable margin of error. Although hypothesis testing deals with tests of equality, the closely related confidence interval approach deals with comparability. The confidence interval calculation can be applied to comparisons of means from samples drawn from normal populations or from any population if the samples are large (thanks to the central limit theorem). First, we calculate the difference between two means from samples from the two population $\bar{x}_1 - \bar{x}_2$, which estimates the difference between the population means $\mu_1 - \mu_2$. Next, we need to calculate the standard error for this difference.

The standard error is calculated as $se = (s_p^2/n_1 + s_p^2/n_2)^{0.5}$, where n_1 and n_2 are the number of values in the first and second samples, and s_p^2 is a variance estimate (s_p^2 from t -test and s_2^2 from one-way ANOVA or MS_{Error}). We have $(1 - \alpha) \times 100\%$ confidence that the true difference between the population means falls within the interval $(\bar{x}_1 - \bar{x}_2) \pm se \times t_{\alpha/2}$, where $t_{\alpha/2}$ is the critical one-sided t -value at the $\alpha/2$ level of significance and degrees of freedom equal to those for our variance estimate s_p^2 .

In ANOVA for the results from the two analysts, $MS_{\text{Error}} = 1.2953$ with 19 degrees of freedom. The means for analyst 1 was 607.8/12, or 50.65 and for analyst 2 was 661.4/12, or 55.12. The difference between the means is -4.47 . The standard error se for the difference would be $(s_p^2/n_1 + s_p^2/n_2)^{0.5} = (2s_p^2/n)^{0.5} = (2MS_{\text{Error}}/12)^{0.5} = (2 \times 1.2953/12)^{0.5} = 0.465$. The critical t -value for a 95% confidence interval is the one-sided, 0.025 level value at 19 degrees of freedom, 2.095. The 95% confidence interval is $(-4.47) \pm (0.465)(2.095)$ or from -5.44 to -3.50 . We have 95% confidence that the results of analyst 1 are between 6.34% ($100 \times 3.50/55.12$) to 9.88% ($100 \times 5.44/55.12$) lower than those of analyst 2 using the assay method. Because the value 0 is not included in the 95% confidence interval, we can conclude at the 5% level that there is a statistically significant difference between the two analysts, the same conclusion we had with ANOVA. However, a difference of 9.88%, the maximum confidence interval limit, might not be large enough for us to reject that the two analysts are comparable in their performance of the assay method. This is a decision that was not possible based solely on ANOVA results.

LINEAR REGRESSION

Those familiar with analytical methods probably have familiarity with “fitting a straight line” through data points. The statistical method generally used is known as

linear regression or ordinary least-squares. Even the simplest scientific calculators and spreadsheet programs contain the methods for determining the slope (m) and intercept (b) of the line relating the dependent variable y (measured with random error) to the independent variable x (without random error), $y = mx + b$. The statistical form of this is $y_i = mx_i + b + e_i$, where e_i is the random error for the observation y_i at a specific value of x_i . The calculations for fitting the line are easy, with $m = [\Sigma(x_i - \bar{x})(y_i - \bar{y})]/[\Sigma(x_i - \bar{x})^2]$ and $b = \bar{y} - m\bar{x}$, where \bar{y} and \bar{x} are the mean values for all the y_i and x_i values, respectively. It is common to have more than a single y value for each x value. A basic assumption is that the variance (error) in the determination of each y_i value is independent of its corresponding x_i value.

As previously indicated, the determination of a drug concentrations in plasma specimens requires the construction of a calibration response curve. This curve is often constructed as a straight line from the measured peak response ratios (y_i) plotted against their respective calibrator concentrations (x_i). The drug concentration in a specimen or the apparent (back-calculated) calibrator concentration is obtained from a rearrangement of the equation for the calibration line (without error) $x_i = (y_i - b)/m$. An example of a calibration curve with

back-calculated concentrations is given the first four columns of Table 10.

It is obvious that the lower end of the calibration curve does not provide an accurate representation of the calibrator concentrations, a problem that does not exist at the higher end of the curve. This problem illustrates what can happen when there is violation of the assumption of equal (homogeneous) variance for the y_i values. In bioanalytical methods, the largest component of the random error can often be attributed to volume errors. One often finds that the standard deviation of the response (y_i) is proportional to the concentration (x_i), that is, $e_i = kx_i$, where k is a constant. This violates the assumption of homogeneity of variance for y_i . To correct for this, we can use a variance-stabilizing transformation. If we divide the equation of the line by x_i , we obtain $y_i/x_i = m + b(1/x_i) + e_i/x_i$. However, $e_i/x_i = K$ is a constant, resulting in equal variance for $y'_i = y_i/x_i$. When y'_i is regressed against $1/x_i$, we obtain a line with slope equal to our desired intercept b and an intercept equal to the desired slope m . The last four columns of Table 10 demonstrate with calibrator data how this transformation provides accurate estimates for the back-calculated concentrations. The variance-stabilized line provides a slope estimate that differs only slightly from that of the original line ($0.938 \rightarrow 0.941$) and an

^bSlope = 0.941; intercept = 0.0834.

intercept estimate that differs more substantially (0.195 \rightarrow 0.0834). The approach of weighted least-squares, available in many advanced regression programs, gives the same results, using a $1/x^2$ weighting, and provides a greater choice for variance stabilization.

A FINAL WORD

The methods presented will hopefully provide a basic foundation for the application of statistics to pharmaceutical problems. Because of space limitations, the discussion has been limited to situations in which known statistical distributions could be assumed (parametric analyses). This is not always the case with real-life data. Fortunately, there are a number of nonparametric, distribution-free methods available to the pharmaceutical scientist to deal with analyses of such data. A general knowledge of statistical methods is a necessity for the pharmaceutical scientist. It is, however, also important for the scientist to realize when a problem or experimental design requires consultation with a statistician. The pharmaceutical statistician has a toolbox of methods considerably more advanced than the few basic methods presented here.

INTRODUCTION

Scope

Statistical process control (SPC) provides a statistical approach for evaluating processes and for improving the quality of these processes through elimination of special causes. When SPC is effectively implemented within a company, benefits can be derived through a reduced cost of manufacture, improved quality, fewer troubleshooting crises, and improved relationships with customers. Process capability is a companion tool—one that can be used once a state of statistical control is achieved—to assess the performance of a process relative to its product specifications. Process capability can be used to determine whether processes are capable of continually operating within their stated specification limits.

These tools have been used successfully in such industries as the automotive and semiconductor industries and have been credited for helping to provide great improvements in quality. They have been used to a lesser extent in the pharmaceutical industry but do provide the same potential for providing improvements in quality. This chapter provides a clear explanation of these concepts and how they can be used in practice. The relevance of these concepts to the pharmaceutical industry and some of the cautions associated with their use will be discussed. Some examples will be provided to aid in the understanding of their use. In addition, some possible reasons why these concepts have been slow in gaining acceptance within the pharmaceutical industry will be discussed.

Basic Principles

A *process* is defined as a set of interrelated or interacting activities that transform inputs into outputs. *Statistical process control* is a set of techniques for improving the quality of its output. Although manufacturing processes first come to mind, SPC can apply to any process, such as services, office procedures, and quality assurance func-

tions. *Process capability* analysis assesses the ability of the process to consistently meet specifications.

In any process, regardless of how well designed or maintained, a certain amount of natural or inherent variability will exist. This natural variability has been called a “stable system of chance causes.” A process operating with only chance causes is said to be in *statistical control*, and the variation is said to be because of *common causes*. Statistical process control evaluates whether or not a process is in statistical control with respect to one or more process or product characteristics.

If an upset occurs in a process (indicated by a spike, sustained shift, or trend in the process mean or by a change in the process variability), then an investigation is initiated to determine the *special cause* of the upset. The special cause, when determined, is either eliminated or controlled by process adjustment. By eliminating or controlling the special causes, process improvement occurs. *Root cause analysis* is a structured investigation that aims to identify a special cause and the actions necessary to eliminate it, and involves the use of a collection of tools including flow charts, brainstorming, cause-and-effect diagrams, and Pareto analysis, as described in other references.^[1,2]

The *control chart* is the basic analytical tool of SPC and is used for first *assessing* a process, then for *monitoring* a process output with respect to on-target control and process variability. A control chart is basically a time plot of a statistic calculated from a variable associated with a process. This variable may either be a process variable, such as temperature or flow rate, or a product variable, such as fill weight or potency. Examples of statistics are an individual measurement, an average of two or more measurements, a percentage of defective output items, a count of defect occurrences in time or space, or a measure of variation such as a range or standard deviation of two or more measurements.

Superimposed on this time plot are the upper and lower *control limits*, traditionally set at a distance of ± 3 times the standard error (SE) of the statistic from the *center line* or process mean. This controls the risk of a false alarm at a low level (a chance of 3 of 1000 if the

distribution is normal). The process is said to be in a *state of statistical control* if the plotted points appear to occur in a random pattern and are contained within the control limits. The centerline and control limits are calculated from retrospective data from the process.

STATISTICAL PROCESS CONTROL

The Shewhart Chart

The *Shewhart Chart* is applicable when the data are numeric and multiple data values are taken at each time point. For discrete parts processes, multiple items are sampled from the process at each time point and measured for one or more characteristics. These multiple measurements constitute a *subgroup*. The number n of measured items in the subgroup is the *subgroup size*. The values of the measured characteristic in a subgroup are denoted as X_1, X_2, \dots, X_n . The subgroup *average* $\bar{X} = \sum_{i=1}^n X_i/n$ is calculated and plotted on the Average Chart (also called the \bar{X} -Bar Chart) as a measure of the process average at that time point. The subgroup *range* $R = \text{Max}(X_i) - \text{Min}(X_i)$ is also calculated and plotted on the Range Chart (also called the R -Chart) as a measure of the process variation at that time point. The two charts are used as a unit and constitute the Shewhart Chart.

On each of the component charts, the average value is represented as a solid line, called the central line (CL). For the \bar{X} chart, the CL is the average of the averages $\bar{\bar{X}} = \sum_{j=1}^k \bar{X}_j/k$, and for the R -Chart, the CL is the average range $\bar{R} = \sum_{j=1}^k R_j/k$, where k is the number of subgroups.

Around the CL are the control limits, set at ± 3 SE of the statistic being plotted. If the statistic value falls outside the control limits, this is a signal that the process is not in a state of statistical control. Because the standard errors are functions of the process standard deviation σ , an estimate of this quantity is necessary. This can be supplied by the average range. The lower control limit (LCL) and upper control limit (UCL) are calculated as follows:

Chart	CL	LCL	UCL
Average	$\bar{\bar{X}}$	$\bar{\bar{X}} - A_2\bar{R}$	$\bar{\bar{X}} + A_2\bar{R}$
Range	\bar{R}	$D_3\bar{R}$	$D_4\bar{R}$

The values of A_2 , D_3 , and D_4 are given in Table 1.

The d_2 factor is used to provide an estimate of the process standard deviation $\hat{\sigma} = \bar{R}/d_2$, where the caret (^) denotes an estimated value. More extensive tables of control chart factors are available.^[3]

Table 1 Control chart factors

Shewhart Chart Example

An example of a Shewhart Chart is shown below for a hypothetical powder fill process. Five vials of product were sampled every hour and the net content of each vial was determined. The Shewhart Chart is shown in Fig. 1. The Average Chart indicates lack of statistical control at subgroups 3, 4, 9, 14, and 17. Further study of the Average Chart indicates a possible shift in the process mean at subgroup 12, and the Range Chart shows an increase at subgroup 6. Subsequent special cause investigation determined that the shift in process mean was caused by a change to a new feed hopper containing powder of a higher bulk density before subgroup 12 (the filling was controlled by volume). A line stoppage before subgroup 6 because of a shift change caused increased variability in the fill weights of the product on startup.

The purpose of SPC is to detect special causes so that they can be eliminated. In this example, two special causes were uncovered: the change in input powder bulk density and the unnecessary line stoppages.

Calculations for the Shewhart Chart

This section illustrates the calculations required to generate the control chart provided in the preceding example. In this case, the control limits were calculated from the available line data. In subsequent phases of SPC, these control limits would be applied to future data as they are measured from the process. The averages and ranges calculated for each subgroup for the current data are in Table 2.

The overall average of the $k=20$ subgroup averages and the overall average range of the subgroup ranges were calculated using the formulas $\bar{\bar{X}} = \sum_{i=1}^k \bar{X}_i/k = 6017.6/20 = 300.9$ and $\bar{R} = \sum_{i=1}^k R_i/k = 51.6/20 = 2.6$. These values were plotted as the centerlines of the Average and Range Charts, respectively.

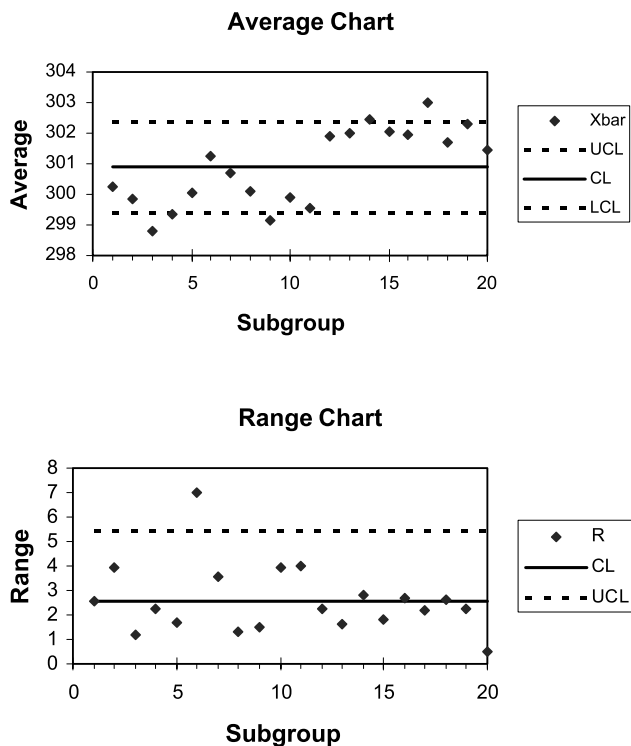

Fig. 1 Shewhart control chart for a hypothetical powder fill process. (Go to www.dekker.com to view this figure in color.)

For a subgroup size of $n=5$, the control chart factors taken from Table 1 were:

n	A_2	D_3	D_4	d_2
5	0.577	0	2.114	2.326

The control chart limits for the Average Chart were:

$$\text{LCL} = \bar{\bar{X}} - A_2\bar{R} = 300.9 - (0.577)(2.6) = 299.4$$

$$\text{UCL} = \bar{\bar{X}} + A_2\bar{R} = 300.9 + (0.577)(2.6) = 302.4$$

The control chart limits for the Range Chart were:

$$\text{LCL} = D_3\bar{R} = (0)(2.6) = 0$$

$$\text{UCL} = D_4\bar{R} = (2.114)(2.6) = 5.5$$

An estimate of the process standard deviation was $\hat{\sigma} = \bar{R}/d_2 = 2.6/2.326 = 1.1$.

Control Chart Design

A basic concept in the Shewhart Chart methodology is the division of observations into *rational subgroups* to

Table 2 Averages and ranges calculated for each subgroup for the current data

Averages over subgroups						300.9	2.6

maximize variability between subgroups and to minimize variability within subgroups. As an example, if we are sampling four bottles from a filling line each hour, it would be better to sample them all at one time, rather than to sample one bottle every 15 min. Sampling over a longer period of time can capture sources of variability other than inherent variability.

Frequency of sampling depends on the dynamics of the process; that is, it depends on how quickly the process reacts to changes in process inputs and on the consequences (costs) of failing to react quickly to changes.^[4] Another consideration is the testing time turnaround, because a high sampling frequency is not useful if the test results are not available before the time that the next sample is taken. Typically, physical measurements may be made in real time whereas chemical measurements may require laboratory assay.

The subgroup size is based on a number of considerations: cost and ease of sampling, cost and ease of measurement, and the need to quickly detect shifts from target of a given magnitude. A subgroup size of four or five is the most common, especially for physical measurements, because it assures that the average value is normally distributed if the distribution of the individuals is reasonably symmetric. If testing is lengthy or expensive, the subgroup size can be reduced to two or three. Large subgroup sizes, such as 10 or 20, are unusual and recommended only in those situations where the control chart must be sensitive to small shifts in the process mean and the testing is rapid and inexpensive.

The chart in Table 3 indicates how quickly the X-Bar Chart would react to a shift of h standard deviations ($h\sigma$), in terms of the average number of subgroups or average run length (ARL), as a function of subgroup size n .^[1] The larger the subgroup size is, the more sensitive the chart is to a given shift.

Table 3 Average run length to detect a shift of $h\sigma$ vs. subgroup size

h	Subgroup size (n)					
	1	2	4	6	10	16
0.5	167.3	92.4	44.0	26.4	12.8	6.3
0.6	124.4	63.9	27.8	15.9	7.4	3.6
0.8	72.3	32.4	12.4	6.7	3.1	1.7

Supplemental Statistical Process Control Rules for Detecting Lack of Statistical Control

The process is in a state of statistical control if the values are within the control limits and the pattern is random. To help detect special causes, a set of supplemental rules is available from the "Statistical Quality Control Handbook,"^[5] and a subset of these rules is given below. The process is deemed "out of control" when:

- 2 of 3 points fall outside the warning limits (shift)
- 8 points in a row fall above or below the CL (shift)
- 6 points in a row are steadily increasing or decreasing (trend)
- 14 points in a row alternate up and down (two feed sources or overadjustment).

To implement these rules, it is helpful to also show on the chart the lines for ± 2 SE (warning limits) in addition to the control limits. These rules should be used with discretion; studies have shown that the use of the supplemental rules causes an increase of "false alarm signals" vs. using the ± 3 SE control limits only.^[6]

Control Charts for Multiple Processes

Many processes consist of multiple streams, such as multiple-head fillers for powder fills or multicavity molds for tablet compression. Each stream must be considered a separate process.^[7] There are two general situations:

- (1) The stream number can be identified at time of product inspection.
- (2) The stream number cannot be identified.

For case (1), a group control chart could be maintained on all streams but it suffices to plot only the two streams corresponding to the highest and lowest values. The chart limits are set up for a single stream and run rules should not be used. If the output of the heads is highly correlated, then a single chart on one stream may be used as a surrogate for all streams.

Case (2) often applies to high-speed fillers with a large number of heads. For this situation, a random sample of a subset of the heads can be taken at each time period. Once per shift (or, more frequently, if necessary), a complete set from all heads (a "head check") should be taken and these data can be examined for necessary individual head adjustments.

There are two types of special causes in multiple processes: those that affect a single head (e.g., plugging), and those that affect all heads (e.g., viscosity). The head check addresses the first kind, and the control chart of

random samples addresses the second kind. Head-to-head variation can be considered a special cause, but one that cannot be eliminated entirely.

Other Control Charts

A standard deviation chart can be used instead of the Range or *R*-Chart, where the sample standard deviation s is calculated as $s = \sqrt{\sum_{i=1}^n (X_i - \bar{X})^2 / (n - 1)}$. The statistic s is considered to be more “efficient” than the range R because s makes use of all the data instead of the two extreme data points in the subgroup. However, the *R*-Chart is easier to use on the shop floor and is recommended for subgroups sizes up to seven, where R is at least 90% as efficient as s . Control chart factors for the s chart can be found in Ref. [3].

The *Individual—Moving Range Chart* is used when the subgroup size is one. If the process deals with bulk product in a batch or a continuous process, only single measurements may make sense because multiple measurements would reflect only the assay and sampling variability, not the process variability. Because there is no measure of variability in a single measurement, the *moving range*, or the absolute difference between two successive individual values, is calculated. The average moving range performs the function that the average range does in the Shewhart Chart. The control limits for the Individual Chart are computed using an A_2 value of 2.66. The UCL for the Moving Range Chart uses a value of D_4 equal to 3.267.

Two alternatives to the Shewhart control chart, which are more complicated to calculate but generally more effective to detect small shifts, are the Cumulative Sum (or Cusum) control chart and the Exponentially Weighted Moving Average (EWMA) control chart. These control charts will not be discussed here, but are described in standard references.^[1,2]

The P-Chart is used when the statistic plotted is the fraction defective p of n product units. The C-Chart is used when the statistic plotted is the count c of defects or occurrences of an event in time or space. These charts are termed “attribute charts” and are also described in standard references.^[1,2]

Developing and Maintaining a Statistical Process Control Program

An SPC program can be valuable when used on processes where production is steady. The best chance for successful application occurs when a team is formed, comprising the plant operators, first-line supervisors, technical support people, and plant management. The team must decide on

the most critical variables to track, and these variables should be kept to a minimum.

Ryan^[2] discusses three phases of control chart usage:

Phase I—retrospective analysis of historical data for process assessment

Phase II—process monitoring in real time to find and control special causes

Phase III—process monitoring to confirm that the process remains in statistical control.

In Phase I, if data are not already available, the first step is to set up a plan for gathering and charting the data. These charts should be kept in the operating area and are usually manually plotted. Operators are encouraged to record all process adjustments as well as to record anything that might have happened to the process. These charts may be part of the operating records. A minimum of 100 data points is recommended before control limits are calculated and placed on the charts.^[2] Because most of the subgroups are of size four to five, this amounts to approximately 20–25 subgroups. The initial plots may simply be Run Charts, where the averages are plotted. The team should be discussing potential special causes that might affect the process variable being plotted.

In Phase II, the team should immediately react to an out-of-control signal and investigate for a special cause. During this phase, the team should record any process information that might be relevant in special cause identification. This phase is complete when the process is in control for an extended period of time with infrequent signals (say, one in every 100–300 subgroups). The control limits should be recalculated if a process change has occurred. They may also be recalculated at some specified frequency, such as every 50 subgroups or annually, depending on how often the observations are taken.

During Phase III, the process is monitored for instances of special causes. When special causes cannot be entirely eliminated, an Out-of-Control Action Plan (OCAP) can be developed for routine use by operating personnel.^[2] The OCAP comprises three features: activators, checkpoints, and terminators. The *activators* define the conditions that signal when the OCAP must be activated, and the control chart usually performs this function. The *checkpoints* instruct the operator to investigate specific items as possible special causes for the out-of-control condition. Once a checkpoint has been identified as a special cause, a *terminator* calls for a specific action to be applied to resolve the problem.

The purpose of SPC is to reduce variability and to improve the quality of process output. Such programs derive benefits through reduced costs of manufacture, better quality, fewer troubleshooting crises, and improved

relationships with customers. In a strict sense, SPC is a tool for getting a process into statistical control, not for making process adjustments. For making process adjustments, while data continue to be charted, the centerline is usually set at the target value and process adjustment schemes are needed. Without these schemes, operators will tend to over adjust. One reference that discusses such manual process adjustment schemes in detail is Ref. [4]. Two summary articles on the same topic can be found in Refs. [8] and [9].

PROCESS CAPABILITY

Defining Process Capability Indices

As stated earlier, a process capability analysis assesses the process performance relative to product specifications. Specification limits are denoted as LSL for the lower specification limit, and as USL for the upper specification limit. In some cases, there is only a single specification limit, either a lower limit or an upper limit.

Two *process capability indices* are in common use, and they are as follows:

- (1) The process-centered index $C_P = (USL - LSL) / 6\sigma_C$
- (2) The process-shifted index $C_{PK} = \text{MIN}[(USL - \mu) / 3\sigma_C, (\mu - LSL) / 3\sigma_C]$

where μ is the process average and σ_C is the standard deviation measuring the inherent process variability. The C_P index can be used only when there are two-sided specifications. These indices are defined so that higher is better.

Figs. 2–4 illustrate the meaning of the C_P index for the following situations: $C_P < 1$, $C_P = 1$, and $C_P > 1$. The three situations can be described as follows:

$C_P < 1$: The $\mu \pm 3\sigma_C$ range of this process distribution (the area under the curve) is wider than the specification limits, so that $C_P < 1$ (see Fig. 2). A large percentage of

Fig. 2 Comparison of process output vs. specifications for $C_P < 1$.

Fig. 3 Comparison of process output vs. specifications for $C_P = 1$.

rejects is produced even when the process is centered and in control. The defects are depicted as the area under the curve outside the specification limits, and the process is clearly not capable of producing a product that consistently meets specifications.

$C_P = 1$: For this process, the $\mu \pm 3\sigma_C$ range coincides with the specification limits; therefore $C_P = 1$ (see Fig. 3). Assuming that the process is centered and in control, the defect rate is 0.27% if the process output is normally distributed.

$C_P > 1$: For this process, the $\mu \pm 3\sigma_C$ range is much tighter than the specification limits, so that $C_P > 1$ (see Fig. 4). The process has room for slight shift and drift without producing defects.

If a process is not centered, than a more meaningful process capability index is C_{PK} . This is shown in Fig. 5.

$C_{PK} < 1$: For this process, $C_P > 1$, but the process is not centered; therefore defects are produced. For this reason, $C_{PK} < 1$ better reflects this situation (see Fig. 5). Another definition of C_{PK} that might be easier to understand is $C_{PK} = |\mu - \text{nearest spec limit}| / 3\sigma_C$.

The relationship between C_P and percent defective (assuming a normal distribution) is given in Table 4.

For these indices to be meaningful as descriptors of process capability, the process must be in a near state of statistical control. A perfect state of statistical control is rarely attainable. A criterion for near-statistical control is that out-of-control signals appear about once in every

Fig. 4 Comparison of process output vs. specifications for $C_P > 1$.

Fig. 5 Comparison of process output vs. specifications for $C_{PK} < 1$.

100–300 subgroups. This is usually the case in Phase III of the SPC program. Until that point is reached, the process capability indices should reflect only the process potential should the special cause variation be eliminated. Some of the many cautions associated with the use of capability indices are described throughout this entry and detailed in Refs. [10] and [11].

Defining Process Performance Indices

Sometimes an analysis of process capability is desired when the process is not in a state of strict statistical control. When this occurs, process performance indices should be used. Process performance indices can be defined as: $P_P = (USL - LSL)/6\sigma_P$, and $P_{PK} = \min[(USL - \mu)/3\sigma_P, (\mu - LSL)/3\sigma_P]$, where σ_P is now the overall standard deviation of the process output characteristic.

For a process that is not in a state of strict statistical control, σ_P is greater than σ_C , the inherent variation, because there is additional variation because of process shift and drift. This additional variation component is σ_S , where the “S” in σ_S denotes special cause variation. Because variances, not standard deviations, are additive, these components can be represented as $\sigma_P^2 = \sigma_C^2 + \sigma_S^2$. Another way to state the objective of SPC is to reduce σ_S as close to zero as possible. One criterion used to assess whether a process is near statistical control is the closeness of the ratio σ_P/σ_C to 1. Table 5 shows the relationship between this ratio and the percentage of total variation represented by special cause variation.

Table 4 Relationship between C_P and percent defective

C_P	% Def	C_P	% Def
0.6	7.19	1.0	0.27
0.7	3.57	1.1	0.097
0.8	1.64	1.2	0.032
0.9	0.69	1.3	0.001

Table 5 Relationship between σ_P/σ_C and the percentage of total variation represented by special cause variation

σ_P/σ_C	σ_S^2/σ_P^2 (%)
1.30	41
1.25	36
1.20	31
1.15	24
1.10	17
1.05	9
1.00	0

For example, when $\sigma_P/\sigma_C = 1.2$, the percentage of special cause variation is 31%, which may represent a practical goal for attaining “a near state of statistical control.”

Estimating Process Capability Indices

To estimate process capability indices from data, the estimates replace the true process values in the following formulas as follows:

The process-centered index

$$\hat{C}_P = (USL - LSL)/6\hat{\sigma}_C$$

The process-shifted index

$$\hat{C}_{PK} = \min[(USL - \bar{X})/3\hat{\sigma}_C, (\bar{X} - LSL)/3\hat{\sigma}_C]$$

where \bar{X} is the estimated process average and $\hat{\sigma}_C$ is the estimated standard deviation measuring the inherent process variability. The estimates of \bar{X} and $\hat{\sigma}_C$ can come from a prior control chart analysis, where $\hat{\sigma}_C = \bar{R}/d_2$.

Use of the \hat{C}_P estimate assumes that the process is centered at or near the exact middle of the specification range of a two-sided specification. This represents the best capability achievable. The \hat{C}_{PK} estimate assesses the process with no assumption that the process is centered, and this estimate is always equal to or less than the corresponding \hat{C}_P estimate. If the distribution of the output is close to a normal distribution and the capability index is based on a large and representative sample size, then acceptance values can be established. Some industries define a process with $\hat{C}_{PK} = 1$ as barely capable and one with $\hat{C}_{PK} = 1.33$ or higher as capable. (Note that a $\hat{C}_{PK} = 1$ represents a situation where the process is centered and the specification range is equal to $6\hat{\sigma}_C$.)

Estimating Process Performance Indices

The estimates of the performance indices are defined analogously to the capability indices as $\hat{P}_P = (USL - LSL)/6\hat{\sigma}_P$ and $\hat{P}_{PK} = \text{MIN}[(USL - \bar{X})/3\hat{\sigma}_P, (\bar{X} - LSL)/3\hat{\sigma}_P]$, using the estimate $\hat{\sigma}_P$, which is the estimated overall standard deviation of the process output characteristic. Thus $\hat{\sigma}_P$, the estimate of σ_P , includes not only the estimated inherent deviation $\hat{\sigma}_C$, but also the estimated variation due to process shift and drift from special causes. Therefore $\hat{\sigma}_P > \hat{\sigma}_C$ for a process not in statistical control.

Process performance indices strictly apply only to the data set being examined because the process is not predictable into the future when it is not in statistical control. However, in practice, the indices are often interpreted to provide an assessment of the process as it currently exists.

If the process is not in a state of strict statistical control (i.e., stable and predictable), every attempt should be made, when practical, to improve control and to put the process into as close to a state of statistical control as possible. If the process cannot be put into statistical control, enough time points should be collected to be able to assess the full degree of shifts and drifts of the process and to determine whether the data are indicative of the long-term process with all of its shifts and drifts. As Pruett and Schneider^[12] indicate, P_{PK} is a measure of process capability over a period of time. If extensive data can be obtained, the ability of the process to meet its specifications can be evaluated, with care, by the estimate \hat{P}_{PK} . If extensive data cannot be obtained, \hat{P}_{PK} can provide only the capability of that particular set of data to meet the specifications.

Before the special causes are fully identified and controlled, \hat{P}_{PK} estimates the process performance that the customer currently experiences, and \hat{C}_{PK} estimates the potential process capability attainable when the process is brought more closely into a state of statistical control. As the process approaches a state of statistical control, \hat{P}_{PK} approaches \hat{C}_{PK} . Similarly, the estimates \hat{P}_P and \hat{C}_P are used when the process is centered within two-sided

Table 7 Sample capability indices that provide at least a 95% confidence that the true process capability is at least 1.00 or 1.33 based on various sample sizes

<i>n</i>	$C_P=1.00$	$C_P=1.33$

100	1.13	1.51
200	1.09	1.45

specification limits, or to reflect what the capability would be if the process were centered.

Precision of Estimates of Capability and Performance Indices

It is important to remember that the capability and performance indices calculated from the data are only estimates and thus have uncertainty associated with them. Confidence intervals can be calculated for these indices to reflect this imprecision.^[11] For example, a $100(1-\alpha)\%$ two-sided confidence interval about the estimated process capability index \hat{C}_P is:

$$\hat{C}_P \sqrt{\frac{\chi_{1-\alpha/2, n-1}^2}{n-1}} \leq C_P \leq \hat{C}_P \sqrt{\frac{\chi_{\alpha/2, n-1}^2}{n-1}}$$

where $\chi_{1-\alpha/2, n-1}^2$ and $\chi_{\alpha/2, n-1}^2$ are the lower and upper $\alpha/2$ percentage points of the chi-square distribution with $n-1$ degrees of freedom.

This interval is constructed to contain the true unknown index C_P with a specified degree of confidence $100(1-\alpha)\%$. For example, 95% two-sided confidence intervals for two different sample values of \hat{C}_P for different sample sizes are as shown in Table 6.

As can be seen from the table, if a sample \hat{C}_P of 1.00 is obtained from a sample of 30 values, then with 95% confidence, it can be stated that the true process capability C_P is between 0.74 and 1.26. If, instead, one is only interested in one direction (e.g., how low the true C_P index might be based on a sample of size n), a one-sided lower confidence interval could be generated.

If, on the other hand, one is interested in determining the minimum acceptable sample process capability index \hat{C}_P required to have some stated confidence $100(1-\alpha)\%$ that the true C_P is above some value (e.g., $C_P=1.0$), one can use the following equation for a particular C_P , sample size n , and risk level α : the minimum \hat{C}_P is $C_P / \sqrt{\chi_{1-\alpha, n-1}^2 / n - 1}$. This can be useful for determining sample sizes during protocol generation where a particular

30	0.74	1.26	0.99	1.67
100	0.86	1.14	1.14	1.51
200	0.90	1.10	1.20	1.46

minimum C_P is required for protocol acceptance. For example, the sample capability indices that would be needed to have at least a 95% confidence that the true process capability is at least 1.00 (or 1.33) based on various sample sizes are shown in Table 7.

Confidence intervals for any of the other indices of interest (P_P , C_{PK} , or P_{PK}) have sometimes been estimated in practice by using the above equations but by substituting the index of interest. However, these intervals should only be considered as approximate. More statistically based approximations for these intervals are discussed in Refs. [13] and [14]. One often used approximate confidence interval for C_{PK} assumes that the distribution of \hat{C}_{PK} is normal and a Taylor series approximation is used to construct a $100(1-\alpha)\%$ two-sided confidence interval for C_{PK} as follows:

$$\hat{C}_{PK} \pm Z_{\alpha/2} \sqrt{\frac{1}{9n} + \frac{\hat{C}_{PK}^2}{2n-2}}$$

where $Z_{\alpha/2}$ is the upper $\alpha/2$ quantile of the standard normal distribution. For example, to generate a 95% two-sided confidence interval, use $Z_{\alpha/2}=1.96$.

As can be seen from the above examples, reported estimates of capability and performance indices based on small sample sizes are potentially misleading and should not be used unless relatively large samples are obtained, or they are accompanied by a confidence interval when reporting the results.

Nonnormal Distributions

The use of the 6σ factor in defining the process capability indices assumes that the data follow a normal distribution. It is important to remember that large values of these capability indices (indicating a very capable process) may be derived from incapable processes when the data are nonnormal. Similarly, data from a quite capable process may result in low capability index values just because the data are nonnormal. Normality of the data can be checked in a variety of ways. Routine plotting of histograms is a good first step in assessing whether the data are normal. Some of the more detailed techniques for determining whether a set of data is normal are: probability plotting, the chi-square goodness of fit test, and the Anderson–Darling statistic.^[15] If it is determined that the data are not normal, four options are available.^[16]

- Apply a transformation to the data to make the transformed data normal. If the distribution is skewed to the right, one might try a log, inverse, square root,

or cube root transformation of the data to make the data normal. If the data are skewed to the left, an exponential, squared, or cubed transformation might be applied. A histogram can be applied before and after the transformation to assess the ability of the transformation to make the data normal. It is important to remember that the transformation must be applied to the USL and LSL, in addition to the data, before computing the capability index of interest.

- Assume a known distribution and use the multipliers that correspond to the 2.5% and 97.5% points for the known nonnormal distribution (to obtain 95% confidence). One common distribution that is effective in fitting a broad range of distributional forms is the gamma distribution.
- Use the index “as is” as a relative measure and note in report to this effect. Even if the data are nonnormal but symmetrical, the calculations are generally reasonable. However, if the data distribution is heavily skewed, one should be hesitant to use this particular option.
- Omit the computation of capability and performance indices because the values so obtained would be misleading.

Process Capability Example

This example studied the process capability of capsule weight for a hypothetical prescription drug. The specification limits were 290–350 mg. Four capsules were sampled from the process every 20 min and weighed. There were 25 subgroups of four data points each for a total of 100 data points. The results are summarized in Fig. 6.

The control chart analysis indicated that the process was in a state of statistical control because none of the averages and ranges was outside its respective control limits. The data distribution (histogram) was deemed reasonably close to a normal distribution (the bell-shaped curve superimposed on the histogram) because the cumulative data distribution was close to a straight line on the normal probability plot.

In this study, the variability estimates were $\hat{\sigma}_P=6.89$ mg and $\hat{\sigma}_C=6.60$ mg, both in close agreement because the process was in statistical control. The \hat{C}_{PK} estimate was 1.32, which was lower than the \hat{C}_P estimate of 1.52, because the process was not exactly centered between the specification limits. The process performance estimates did not apply because the process was in statistical control, but were calculated by the package and were close to the capability estimates. (Note: In the Minitab output, the estimates do not have the caret (^) over the symbol, but they are in fact estimates.)

If the process were not in a state of statistical control (stable and predictable), then the \hat{P}_P and \hat{P}_{PK} estimates

Capsule Weights

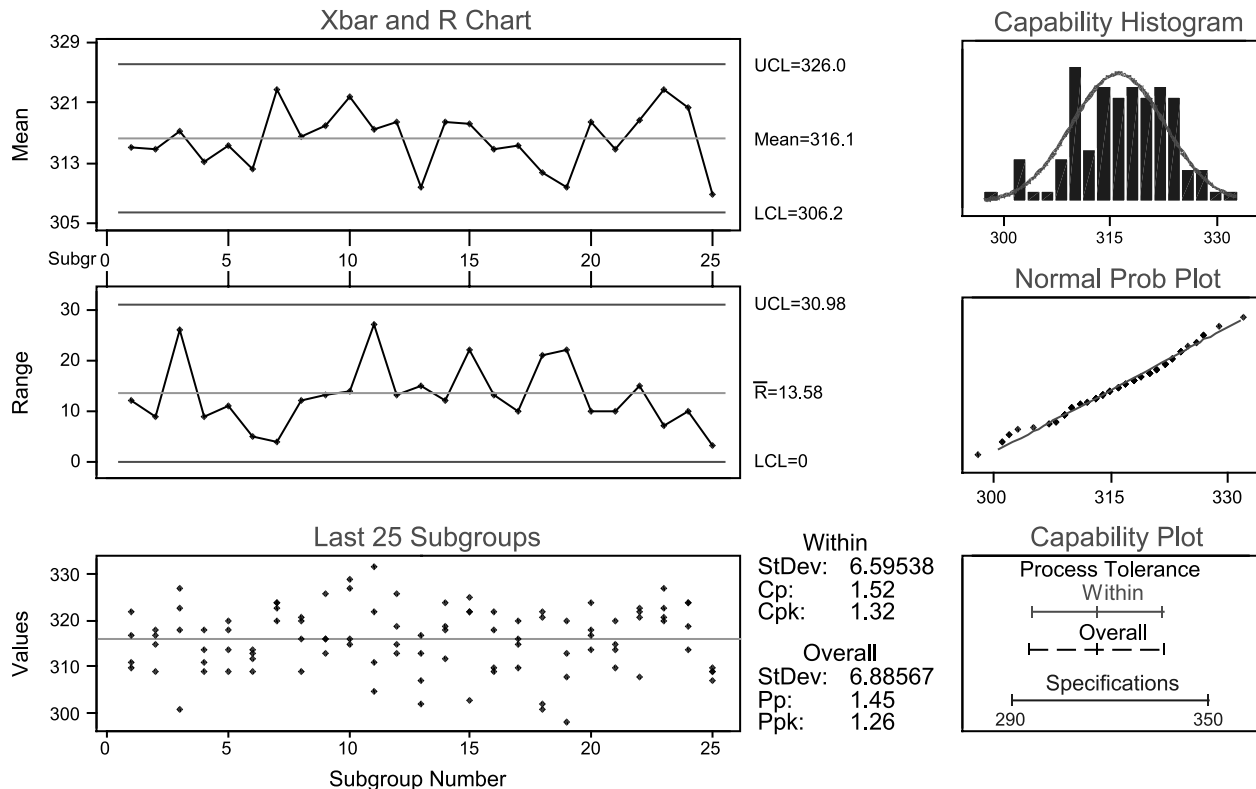

Fig. 6 Summary of capsule weight data using the statistical package, Minitab®. (From Minitab Inc., State College, PA. For details, refer to www.minitab.com.) (Go to www.dekker.com to view this figure in color.)

could be used to judge the process performance at the time the data were collected. The \hat{C}_P and \hat{C}_{PK} indices could be used to assess the process potential if the process were brought into a state of statistical control.

Relationship Between Statistical Control and Process Capability

To summarize, it is important to remember that a process may be in statistical control but still not capable. In a strict sense, it is not appropriate to talk about whether a process is capable if it is not in a state of strict statistical control (because it is not stable and predictive of the future); in practice, the indices are often used to provide an assessment of the process as it currently exists. Caution has been given to the reader to make sure that before an assessment is made of a process that is not in statistical control, enough data have been collected to cover the full range of shifts and drifts in the process. With this information in hand, it is possible to claim, with some

caution, that a process is capable of staying within specifications although it is not in statistical control. However, even though the process may be capable, there are still many benefits in working toward the elimination of all special cause variation.

APPLICATION TO PHARMACEUTICALS

Typical Applications

The concepts discussed in this paper are appropriate for many applications in pharmaceuticals. Some of these areas are as follows:

- Drug potency
- Other finished product attributes (e.g., content uniformity, dissolution)
- Tablet/capsule in-process characteristics (weight, thickness, hardness, disintegration, etc.)

- Powder characteristics (mean particle size, bulk density, etc.)
- Microbial counts
- Drug content application (nasal spray, etc.)
- Fill weight and fill volume
- Air/oxygen-purged systems
- Leachables, residuals
- Liquid characteristics (viscosity, refractive index, etc.)
- Consumer complaints, industrial safety measurements, etc.

Bringing processes into or near a state of statistical control will improve processes by making them less variable centered closer to target, and allow the manufacturer to make a product that will more consistently meet product specifications. This benefits both the manufacturer and the consumers who use their products. The use of SPC methods to evaluate and to improve processes not only can be applied to product characteristics such as tablet weight and tablet hardness, but also to product performance measures such as consumer complaints, line down time, and industrial safety measurements. An SPC approach to process improvement can also lead to reductions in fill overages, reductions in waste, as well as reductions in batch failures. By eliminating special cause variability, it becomes easier to monitor a process to ensure that new special causes do not find their way into the process.

As mentioned earlier, as part of a process capability study, an assessment of variability is conducted. Variability may include both process and measurement variability. This may be especially important when measuring such attributes as potency, content uniformity, and dissolution. It is important to be able to separate process from measurement variability during any investigation of how to improve processes. The samples may need to be tested in a designed fashion to be able to correctly separate these sources of variability. Measurement variability can be independently addressed through assay validation studies.

Analysis of In-Process Data

Control charts are an excellent analysis tool to both monitor and improve in-process performance during process development and later during production, where it is desired to follow process characteristics over time within batches or runs. The most common examples of tablet process characteristics that are measured in-process are weight, thickness, and hardness. The parameters measured need to be controllable so that adjustments can be made. During the initial runs, it is desirable to limit process adjustments to a minimum to observe the process

in its natural state. Any adjustments made should be recorded and explained. Out-of-limit results should never be removed prior to performing a process capability analysis. If special cause variation is detected, then process improvements should be made to eliminate the special cause variation.

For new products, capability should be evaluated and improvements made to the process during development and scaleup, before validation is performed. It should be conducted on the actual full-scale equipment that will be used during routine production. Our experience has been that when evaluating in-process tablet and capsule parameters during production, a good setup is important to ensure that the process starts out at the target value. Additionally, the practice of 1) shutting down the line for breaks and lunch and 2) allowing hopper runout during processing can cause added variability because of segregation of the powder.

Product flow characteristics and interdependencies between parameters, such as tablet weight, thickness, and hardness, may prevent the parameters from each being in strict statistical control. Special studies testing weight, thickness, and hardness on the same tablets will aid in better understanding this interrelationship between these product characteristics. For such characteristics, the in-process specifications may be on either the individual values or the averages (e.g., the average of 10 hardness values), or both. When the average is being evaluated, process capability indices may not be appropriate for evaluating the ability to meet specifications based on individuals.

For example, some process monitoring schemes use an average of 10 tablets to track tablet weight. The 10 tablets are sampled and measured in a single weighing operation at each sampling time, and the average weight is computed and plotted. In this situation, the state of statistical control of tablet weight can be assessed using Individual Moving Range Charts on the tablet averages, but such data may not be applicable for process capability studies when the specification is based on individual tablets.

It is important to remember that a process may be in statistical control but still not capable. Range studies for the critical parameters are an effective way to determine whether the specification limits are tighter than they need to be, or, if no specifications exist, to aid in their development. A range study is intended to determine the high and low ranges for which the parameter is able to demonstrate an ability to meet end-product requirements; for example, high and low hardness ranges that meet both dissolution as well as physicals (e.g., no chipping) help to define appropriate in-process specification limits. If the process is not capable, this may be

because the specifications had originally been set at $\pm 3\sigma$ limits and not what defines acceptable product, as is the purpose of a range study. If this is what was done, capability indices of around 1.0 must be expected.

Analysis of End-Product Data (e.g., for Validation, Annual Product Review, etc.)

Capability and performance indices are appealing as a management process assessment tool because they tie together the process performance (as measured by the sample mean and sample standard deviation) with the product specifications into a single measure. Process performance indices are sometimes used as acceptance criteria during validation, as well as Annual Product Review; however, they need to be used very carefully. Sample sizes may be too small to provide reliable estimates, especially if these indices are used to determine the pass/fail of a validation study or an Annual Product Review. Emphasizing the use of capability indices without the efforts required to initially put the processes into statistical control misses the point. Although not recommended by the authors as strict acceptance criteria for validation or Annual Product Review, capability indices, if used carefully, do provide a useful yardstick for comparison of performance over time periods, or for comparison between products for helping in determining priorities for process improvement efforts. These indices also provide a yardstick to measure the effect of any improvements made to the process in a 'language' that can be easily understood. There are also times when there are just better ways to define process capability for solid dosage forms, possibly by tying it to the end-product test requirements [e.g., the ability to meet the multiple-stage United States Pharmacopeia (USP) tests for content uniformity and dissolution].

The use of common pharmaceutical ingredients and the tendency to "gang test" assays in the laboratory may prevent many of our end-product attributes from being in strict statistical control when measured over time. Therefore it is not recommended that a validation study or Annual Product Review require that a process be in statistical control to be considered acceptable, not even for in-process parameters such as tablet weight, thickness, and hardness. Processes that are not in a state of strict statistical control can be capable of consistently meeting specifications and can be validated. However, if processes are not in statistical control, efforts should always be made to eliminate special causes and get them into as near a state of statistical control as possible. The validation and Annual Product Review data can even be helpful in determining how processes can be improved.

Although these comments have been applied to end-product data, many of these same comments also apply to in-process data as well.

Limitations Within Pharmaceuticals

As discussed earlier, processes in the pharmaceutical industry may be difficult to always get into a state of strict statistical control. Interdependencies may exist between attributes such as the weight, thickness, and hardness of in-process tablets because of product flow characteristics within the batch. Data from sequentially generated batches may be dependent because of the use of common raw materials, or being tested on the same day. But the benefits derived from using the techniques discussed in this entry to improve existing processes and to keep them under control are many. The effort is worth the hard work required to do it.

Nash^[17] points out that what might be possible in other industries may not always be possible for pharmaceutical processes in that a C_{PK} of 1.33 may not always be achievable. Specifications should be customer-directed limits that ensure safety and efficacy, not limits to control the consistency of process. Internal control limits should be used for this purpose. Many of our specifications are either provided to us by the USP or influenced by the Food and Drug Administration (FDA), where industry is encouraged to set specifications as tight as the process will allow. Companies are sometimes asked to agree as to what they view as tight specifications before the full experience that comes with additional production has occurred. In addition, once stability changes over time, batch processing differences, slight biases in the analytical method, and typical measurement and process variability are accounted for, defective levels may not always be in the parts-per-million range as is required for a C_{PK} of 1.33. In fact, if measurement error is large, arbitrary C_{PK} goals may actually be impossible to meet no matter how much the process is improved.^[11]

Because, in the pharmaceutical industry, being the first to market a new drug is of utmost importance, taking the time to put processes into statistical control is too often perceived by companies as slowing down the process of product introduction and not as added value. This attitude needs to change. Companies may also feel that their reward for improving process control and reducing variability is that the FDA will tighten specifications further, thereby risking the production of out-of-specification product. A company's interest in improving processes is often discouraged by a need to revalidate or refile with the FDA whenever significant changes are made to the filed NDA. The authors feel that there needs to be discussions between industry and the FDA on these

issues so that industry is rewarded for the improvement of their processes and everyone, most importantly the consumer, wins. This need for cooperation between the FDA and industry to move the pharmaceutical industry toward real improvements was voiced by Woodcock of the FDA in Ref. [18].

CONCLUSION

The use of SPC to help improve processes and the use of process capability to evaluate the ability of processes to routinely meet specifications are described in detail. They are companion tools that should be used in concert. These tools are described in sufficient detail to allow interested practitioners to correctly apply them within their workplace. Examples of their use are provided for reinforcement as are the assumptions being made when using them. Some of the limitations associated with their use are also discussed, especially in the context of application within the pharmaceutical industry.

With the writing of this entry, the authors hope to encourage the proper use of these important process improvement and process evaluation tools, especially within the pharmaceutical industry. We also hope that some of the barriers to their implementation within the pharmaceutical industry that were discussed within this entry can be overcome through cooperation with the FDA and a mutual desire to improve pharmaceutical processes.

Sterilization by Dry Heat

Andrea Chieppo

Thomas Kupiec

Analytical Research Laboratories, Oklahoma City, Oklahoma, U.S.A.

INTRODUCTION

Sterilization means the destruction of all life. The aim of sterilization is to destroy the ability of microorganisms to survive and multiply with the oldest and most recognized agent of destruction being heat.^[1] Dry heat is the method of choice for sterilizing heat-stable items that might not be adequately penetrated by steam or are damaged by moisture.^[2] Dry-heat sterilization is frequently used in the pharmaceutical industry; items often sterilized by dry heat include powders, oils,^[3] petrolatum, glassware, and stainless-steel equipment.^[2]

Dry-heat sterilization is generally a less complicated process than steam sterilization; it is, however, relatively slow and requires higher temperatures and/or longer exposure times. This is because of the fact that microbial lethality is lower with dry heat than that for steam at the same temperature.^[2] There are various temperatures and periods of treatment for dry heat depending on the pharmacopoeia. The U.S. Pharmacopoeia (USP) states that the dry-heat sterilization process for containers for sterile pharmaceutical products should be at a temperature of 160–170°C for a period of 2 to 4 hr. The British Pharmacopoeia states that items sterilized by dry heat should be kept at a temperature not less than 160°C for at least 1 hr. For the Pharmacopoeia Nordica, the recommendation is 30 min at 180°C. Different materials and sterilization equipment used account for the discrepancies between these pharmacopoeias, but there is also a lack of sufficient information concerning dry-heat sterilization.^[4]

Dry-heat processes have two main targets: microorganisms and their by-products, pyrogens or endotoxins. Depyrogenation is the process that destroys the chemical activity of these by-products. Destruction of microorganisms and endotoxins by dry heat is considered an oxidative process, which is almost a combustion.^[5] Depyrogenation requires a higher temperature than sterilization and can be summarized as follows:

If an effective dry heat depyrogenation is performed, sterilization generally is achieved as well. Effective dry heat sterilization can be performed even without achieving depyrogenation. If moist heat sterilization is performed, in normal operating conditions depyrogenation is not achieved.^[5]

DRY-HEAT STERILIZATION KINETICS

Sterilization is a probability function. In the pharmaceutical industry, an item is deemed sterile if there is less than 1 chance in 1,000,000 that viable microorganisms are present in the sterilized article or dosage form. Therefore there is a 10^{-6} probability of nonsterility.^[6] In all sterilization processes, the inactivation of microorganisms develops as a first-order chemical reaction, i.e., at a rate which is approximately logarithmic.^[7]

The following equation typically describes the order of microbial death:

$$K = 1/t(\log N_0 - \log N)$$

where K =a constant, assuming logarithms to the base 10 and depending on the organism, temperature, and substrate, t =time of exposure in min, N_0 =initial number of viable organisms, and N =number of viable organisms at the end of the time interval.^[7]

Using natural logarithms, the exponential form of the equation is:

$$N = N_0 e^{-Kt}$$

It was found that a 90% reduction in the microbial population resulted in the following equation for K :

$$K = 1/t(\log N_0 - \log 0.1N_0)$$

$$K = 1/t(1) = 1/t$$

$$t = 1/K$$

Time t is defined as the decimal reduction time or D value. Therefore

$$D = 1/K \text{ or } D = 1/10$$

Fig. 1 shows a simplified way to determine the D value where the amount of time can be determined to reduce the microbial population by 90%.^[7]

The kinetics of dry-heat treatments is comparable to that of moist heat sterilization. The organisms that are considered to be representatives for dry-heat sterilization processes are spores of *Bacillus subtilis* var. *niger*.^[4] A D_{170} value, which is the time needed to give a 90% reduction of the spore population at 170°C, of at least 1.5 min may be assumed for these spores.^[6]

Fig. 1 Microbial death rate curves that illustrate concept of decimal reduction (D values) and probability of survivors. (From Ref. [6].)

F_H Concept

For dry-heat temperatures other than 170°C , F_H values are used. The F_H concept is comparable to the F_O concept for moist heat sterilization and references lethality to equivalent times at 170°C . F_H values are shown in units of minutes or seconds, and the calculations of F_H use the same equations as the calculations of F_O . The only difference is that a z value of 20°C is substituted for 10°C .^[6]

DRY-HEAT STERILIZATION PROCESSES

Great strides have been made in developing and improving other methods of sterilization, but little has been accomplished where dry-heat sterilization is concerned. Sterilizers used today are still basically the same as they were a decade ago.^[1]

The two types of processes currently used in dry-heat sterilization include: 1) dry-heat batch sterilization/oven sterilization and 2) dry-heat tunnel sterilization. Process 1 is the type of dry heat unit widely used in the pharmaceutical industry; it uses the principle of convective heat transfer to heat the load. Process 2 is only found in large-scale processes, and the main application of this process is in the sterilization and depyrogenation of glass.^[6]

Convection Heating Processes

In the pharmaceutical industry, large-scale industrial ovens are used. These large-scale processes usually operate to sterilize only because higher temperatures are

required for depyrogenation and this would be prohibitively long.^[6] Convection heating occurs when heat is transferred through a medium by motion of its parts. The two types of convection heating include natural and forced convection heating. Natural convection heating happens as a result of the buoyancy forces generated by differences in density. In forced convection heating, high-efficiency particulate air (HEPA)-filtered air is heated by passage over the electric heating elements of the oven and then this heat is transferred from the air to the product by forced convection.^[2] The basic equation for convective heat transfer is:

$$q/c = \bar{h}_c A \Delta T$$

where q/c = the rate of heat transfer by convection (BTU/hr), \bar{h}_c = the average unit thermal convective conductance (BTU/hr ft^2 $^\circ\text{F}$), A = area (ft^2), and ΔT = the difference

The main features shown in the sketch are

1. Air-circulation fan
2. Water-cooled battery (for the cooling phase)
3. Circulation HEPA filters
4. Launch/recovery bulkheads
5. Trolley and load
6. Discharge duct
7. HEPA filter on the discharge duct to prevent back-flow contamination
8. Variable-speed fan for chamber pressurization (proportionally controlled)
9. Prefilter and HEPA filter on the chamber pressurization loop
10. Electric heater (proportionally controlled)
11. Four flexible Pt100 4-wire RTDs
12. Main control Pt100 4-wire RTD
13. Pressure transducer

Fig. 2 Dry-heat batch sterilizer. (From Ref. [4].)

Fig. 3 Example of a batch process. (From Ref. [2].)

between the surface temperature and the temperature of the fluid at some specified location ($^{\circ}\text{F}$).^[2]

Fig. 2 shows a schematic diagram of a modern forced-convection batch sterilizer. The unit is a two-door sterilizer where the unloading door leads to the sterile area. The pressure inside the chamber must continuously be controlled so that the inside is always slightly higher than the pressure in the nonsterile loading area and slightly lower than the pressure in the sterile unloading area.^[5]

There are four stages involved in oven sterilization. They are 1) drying, 2) heat-up, 3) exposure, and 4) cool-down. During the drying stage, moisture is driven off the product to the atmosphere until the air temperature in the sterilizer is around 80°C . At this point, a baffle closes which allows the temperature within the oven to reach the operating level; this is the heat-up phase. Exposure starts the moment the sterilization thermal sensor reaches the set temperature. After the timed exposure period, the heating elements switch off and cooldown begins. Fig. 3 shows a normal batch process.^[6]

Dry-Heat Tunnel Sterilization

Dry-heat tunnel sterilization is a continuous conduction process in contrast to the batch processes in ovens. A continuous conduction process is one in which a predetermined quantity of items is subject to a continuous conduction cycle at a predetermined rate to effect sterilization and/or depyrogenation.^[2]

Conduction heating occurs via two different mechanisms. The first mechanism is accomplished by molecular interaction where molecules at a higher energy level impart energy to molecules at a lower energy level.^[2] The second mechanism takes place through “free” electrons. The ability of different solids to conduct heat varies directly with the free electron concentration. The solids with the highest amount of free electrons are pure metallic solids, and those solids with the lowest concentration are the nonmetals; therefore pure metals are the best conductors of heat.^[2]

Dry-heat tunnels differ from ovens because energy is not lost to heating and reheating between cycles as occurs with ovens. For a majority of the time spent in the tunnel, the product is subjected to rising temperatures, unlike ovens where the product is held at a constantly maintained exposure temperature.^[6] Tunnels basically consist of a thermally insulated “tunnel” which directly connects an upstream cleaning machine to the downstream sterile area. Inside the tunnel is a horizontally rotating transport belt made of a stainless-steel mesh. When a product is sterilized in a tunnel, it is dried, heat-treated by radiant heat or hot air, and then cooled. A typical tunnel sterilization exposure time is 3 or 4 min at 300°C or more. Whether radiant heat or hot air is used, the internal part of the tunnel must remain pressurized by ventilation at an intermediate pressure level that is between the sterile downstream system and the loading room.^[5] Fig. 4 shows a comparison of the two main types of sterilizing tunnels.

Radiant-heat sterilization tunnels

In the pharmaceutical industry, radiant-heat tunnels have had extensive usage. During this process, energy flows from a high-temperature body to a lower-temperature body and the heat is emitted in the form of finite batches of energy without the aid of an intervening medium.^[2] Infrared tunnels transmit heat by exposing the surface of items to radiation by direct rays. This is accomplished by infrared heaters, located in the roof of the tunnel; when products pass through the tunnel, their surfaces are heated along with the internal surface of the tunnel itself. This heat is then diffused throughout the product by radiation, conduction, and turbulent airflow.^[6]

The basic transfer equation for radiant heating processes is as follows:

$$qr = \sigma AT_1^4$$

where qr = rate of heat flow in BTU/hr, A = surface area of the emitting object in ft^2 , T_1 = surface temperature of the emitting object in degrees Rankine, and σ = Stefan-Boltzmann constant 0.174×10^{-8} BTU/hr ft^2 $^{\circ}\text{R}$.^[2]

There are disadvantages of IR tunnels; they are large, their belt speeds are slow, product heat-up may be less uniform, and they may create particulate problems. These particles are generated from the deterioration of the heating element and the moving belt. This problem can be helped by installing HEPA filters at the entrance of the tunnel and at the cooling zone junction.^[6]

Hot-air laminar flow sterilization tunnels

The most effective means for the sterilization of air is incineration. In laminar flow (LF) tunnels, heating occurs

Fig. 4 Sterilizing tunnels. (From Ref. [5].)

by the circulation of hot filtered air, which is forced onto the product. The air is then withdrawn by a circulation fan and leaves the product through heating elements below the transport belt and then is brought back into the tunnel through HEPA filters.^[5] This sweeping action of the laminar airflow helps contribute to the removal of particulate contamination. The air speed within the LF tunnel remains around 0.5 m/sec. Laminar flow tunnels also have the advantage of quicker heating resulting in shorter process time. This fast heat transfer also contributes to a lower risk of product contamination from particles.^[6]

From the point of view of handling the product, continuous tunnels are more favorable than batch ovens. The main reason for this is that there is no batch work required after the unpacking of the components and loading of them into the tunnel until the packaged product is removed from the line after filling. This is important in large-scale productions, but for easier isolation of the sterile area, batch ovens are better. This is because of the fact that there must be a continuous flow of air through the open connection between the sterile area and the tunnel. The pressure of the sterile area must always remain higher than that of the tunnel. A large difference between

the two would cause an excessive escape of air from the sterile area to the tunnel resulting in the disturbance of the laminar airflow and temperature inside the tunnel.^[5]

EFFECTS OF DRY HEAT ON MICROORGANISMS AND ENDOTOXINS

Inactivation of Microbial Populations

As mentioned earlier, inactivation of microorganisms occurs by oxidation, but other possibilities must also be considered. One possibility is the effect on DNA. In *B. subtilis* spores, sublethal temperatures have been shown to induce mutants as a result of depurination. There are also claims that genetically determined differences in water content could result in the dry-heat sensitivity of spores.^[8] A great amount of interest has been generated relating the water activities of spores with their thermal resistance. The water content of dry microbial cells is important in regards to their destruction rate, and water content is determined by the relative humidity of the atmosphere surrounding the cells; therefore the destruction rate varies

Sterilization by Dry Heat

with the relative humidity of the system. In dry-heat sterilization, water is not present in the liquid state. If the relative humidity is 100%, then some water is present in the liquid state. Therefore the relative humidity of a dry-heat sterilization system can be any value between 0% and 100%. To establish the relative sterilization effect in dry-heat sterilization, the relative humidity conditions must be known in addition to the temperature.^[1] At equilibrium, the water activity (A_w) inside the cell is equal to the relative humidity of the atmosphere surrounding the microbial cell.^[8] Water activity is used to describe the relative water availability inside a microbial cell or spore and is related to the concentration and is expressed as a fraction of the pure component in the standard state where:

$$A_w = 1$$

When reporting on dry-heat test data, relative humidity is measured and controlled instead of water activity. This is because of the fact that biological materials more closely parallel vapor pressure than water content, and vapor pressure of the gas atmosphere surrounding dry microbial cells is more easily measured and controlled than the water content inside the cell.^[1]

There are three primary and three secondary variables involved with the mode of action of dry heat. Temperature, water content, and time are the primary variables, and the secondary variables are open and closed systems, physical and chemical properties of the microorganism and adjacent support, and the gas atmosphere.^[8]

Effect of temperature

The most important variable in dry-heat sterilization is temperature. Temperature, which is the measure of the heat energy level, is a function of time. One measure of the change in destruction rate with temperature is the z value. The z values for dry-heat inactivation of microbial spores have been reported from about 15°C to 30°C.^[8]

Effect of microbial water content

As discussed earlier, water has a direct influence on the resistance of microorganisms to dry-heat destruction. The destruction rate of spores is a function of the quantity of water in the cell at the time of heating. This water content is only constant under certain conditions and in most conditions, the moisture content of the cell can change so that the secondary variables cause confusion in analysis of results. The water vapor pressure in the atmosphere surrounding the cell determines the movement of water to or from microorganisms on surfaces. Research found that when the humidity in air passing over spores was in-

creased from 0 to 0.2, the D value also increased by a factor of 100. Spores of intermediate moisture content with an RH between 0.1 and 0.6 were found to be more resistant to the effects of heat at temperatures between 100°C and 135°C than spores of either greater or lesser moisture content.^[8]

Opened and closed systems

Opened and closed systems were first suggested to indicate the relative control of the heating environment on water loss or gain of spores.

In an open system, the atmosphere surrounding the spore determines the spore water content. In this system, cells are heated, and during this heating time, water may be lost or gained by the cell. The cells can gain or lose water either rapidly or slowly, depending on the physical system and the nature of the spore.^[8]

In a closed system, the spore water content is not influenced by the heating environment, but is more a function of condition inside the enclosure. Closed systems are different in that water movement and water availability to the cell are restricted. The quantity of water that is initially present in the enclosure limits the quantity of water that is available or that can move to or from the cell. Initial water content and enclosure volume of the closed system are two important parameters. The relative humidity of the atmosphere in the enclosure at the time of sealing determines the water concentration in the cell during heating as well as the total volume of the enclosure. Changing either of these parameters will alter the relative humidity, which then alters the water content in the spore during heating.^[8]

Dry-Heat Destruction of Microorganisms Associated with Soil

There are two groups of microorganisms that accumulate on an object when it comes in contact with people and air. The first group includes naked or unprotected microbial cells from human or animal origin. The second group is made up of spores found in particles of dust or dirt that fall on the object being sterilized. These spores come either from the air or from the activity of persons working near the object. The naked microbial cells of the first group are generally easily killed by dry-heat sterilization, but the spores found in soil particles can be difficult to kill. Recent findings on the dry-heat destruction characteristics of microflora associated with soil particles include the following:

1. Microorganisms found in soil are widely variable, having different survival characteristics.

2. Different organisms found in soil are highly resistant to dry heat, including *Bacillus xerothermodurans*, which was found to have a $D_{125^{\circ}\text{C}}$ value of 139 hr.
3. Some organisms can become more resistant to heat when encapsulated in particles, such as *B. subtilis*.
4. It is estimated that 1 spore in 10^3 and 10^5 is extremely resistant to dry heat when found in soil.
5. The bound water in soil particles may overshadow the effect of the humidity level on the destruction rate of the spore.^[8]

The possible variation in numbers and species of microorganisms found in soil and the physical conditions of their location are unlimited. Spores found in soil can be located at any point on or within the particle. Spores can become completely encapsulated in soil particles through the various soil wetting and drying cycles, which can increase resistance by a factor of 10 .^[8]

Destruction of Endotoxins

Bacterial endotoxins, or pyrogens, are substances that will cause a variety of symptoms such as a rise in body temperature when injected in large amounts into human or animal bodies. In pharmaceutical products and medical devices intended for parenteral injection, the absence of endotoxins has equal or greater importance than sterility. None of the other large-scale sterilization methods, such as saturated steam, gamma radiation, and ethylene oxide, are capable of destroying endotoxins.^[6]

All microorganisms seem to be capable of producing pyrogens, but the most potent forms of pyrogens are associated with gram-negative bacteria. Located externally to the peptidoglycan cell wall of gram-negative bacteria is a loosely structured envelope. The outer layer of this envelope is made up of lipopolysaccharides linked to phospholipids and proteins that act as a permeability barrier that stops the diffusion of exoenzymes into the greater environment. It is the lipopolysaccharide fractions of the cell envelope that have been shown to stimulate the pyrogenic response and are termed bacterial endotoxins. Purified endotoxin, which consists only of lipopolysaccharide, is pyrogenic in lower doses than naturally occurring endotoxins. There are three distinct chemical layers of lipopolysaccharide; they include an inner core called lipid A, an intermediate polysaccharide layer, and an outer polysaccharide side chain. Lipid A is the region that is responsible for pyrogenicity and consists of a highly substituted disaccharide of glucosamine.^[6]

The dry-heat destruction of endotoxins is complex and poorly understood. Most evidence has shown that destruction follows second-order kinetics with an initial high

rate of destruction followed by a slower terminal rate.^[6] The kinetics of dry-heat destruction for lipopolysaccharide are expressed in terms of D^1 and D^2 , for the initial and secondary first-order reaction rates, respectively. Previous research found that there was greater reduction in the dry-heat resistance of lipopolysaccharide in whole cells than that in the semipurified state. The D^1 value for the whole cells was found to be 1.6, and the D^2 value was 12. In the semipurified state, D^1 was 3.7 and D^2 was 29.4. Thus the rate of the destruction was two times faster when whole cells were used.^[9]

There is basically no endotoxin destruction at temperatures below 80°C , and the D values can be as high as 20 min for dry-heat temperatures of around 170°C . The second-order models give a better estimate of endotoxin destruction kinetics at temperatures above 250°C than in the 170 – 250°C range.^[6] Generally, the following conditions are required for endotoxin destruction:

230°C —60 to 90 min.
 250°C —30 to 60 min.^[5]

The USP and FDA both state that a claim to depyrogenation should be supported by evidence that any endotoxin present on an item prior to treatment has been inactivated to no more than $1/1000$ of the original amount or a three \log_{10} reduction. At 170°C , the minimum time required to obtain three \log_{10} reductions is between 3 and over 66 hr. At 250°C , six \log_{10} reductions have been demonstrated. For this reason, depyrogenation cycles need to be developed and validated empirically. However, the USP recommends a temperature of at least 250°C .^[6]

DISADVANTAGES OF DRY-HEAT STERILIZATION

Dry heat should be used only for materials that cannot be sterilized by steam either because the moisture would damage the materials or they would be impermeable to it. There are many complicating factors associated with dry-heat sterilization. The process of steam sterilization is accomplished by saturated moisture; in dry-heat sterilization, the moisture can vary considerably. Because of the loss of moisture, the death rate of spores might change with the continued application of heat.^[1]

Although air is the least expensive means of sterilization, it is not the best heat transfer medium. In oven sterilization, there are several drawbacks. One drawback is the lack of uniformity of temperature within the oven. Hot air has a tendency to stratify and poorly penetrate masses of cooler material, but moving the air stream can accelerate heat transfer. Slow heating and cooling down

Sterilization by Dry Heat

because of low heat transfer rates from air to product is another problem with ovens that leads to longer sterilization cycles. Other disadvantages of dry-heat sterilization can occur because of the high temperatures, which can cause heat damage or even charring of materials. Materials can also be damaged due to oxidation because the medium that facilitates this destructive action also augments its deleterious effects.^[1]

CONCLUSION

Although much work has been performed to improve and develop other methods of sterilization, very little has been accomplished in the field of dry-heat sterilization. The process is time consuming and difficult to control because of the temperature stratification and slow heating rate.^[10] Dry heat is still the agent of choice for sterilizing items that might not be adequately penetrated by steam and that will tolerate high temperatures, such as oils, petrolatum, and closed containers.^[2]

The development of the infrared radiation tunnel in recent years has opened new possibilities for using dry heat in high-temperature short-time sterilization processes.^[4] The main advantage of dry-heat sterilization is its penetrating power. It is not as corrosive as steam for metals and sharp instruments, and it does not erode ground glass surfaces, which allows glass to be sterilized at much higher temperatures for shorter periods of time.^[1]

Sterilization by Ethylene Oxide

Terezinha de Jesus Andreoli Pinto

Universidade de São Paulo, São Paulo, Brazil

INTRODUCTION

The biological activity of ethylene oxide (EtO) was initially observed by Cotton and Roark,^[1] who detected it as an insecticide, in concentrations ranging from 3.2 mg L^{-1} to 32.0 mg L^{-1} . In 1937, Gross and Dixon^[2] requested the patent of EtO as a sterilization method due to the considerable experimental evidences it presented.

The first EtO commercial application was related to spices sterilization and/or fumigation.^[3–7] Phillips and Kaye^[8] conducted a series of studies using EtO, focusing on the sterilization of material with thermal resistance problems.

Although its posterior industrial applications included pharmaceutical and cosmetic products, packaging materials and raw materials of biological origin,^[9] EtO is predominantly used in the sterilization process of medical devices, such as intravenous sets, cardiopulmonary and anesthesiology devices. In the hospital environment, the EtO largely contributed as one of the main agents responsible for the controversial increase in the reutilization of single-use medical devices.

ETHYLENE OXIDE CHARACTERISTICS

EtO (oxirane, epoxyethane, and dimethylene oxide) is a colorless gas condensing at low temperatures to a mobile liquid. It is miscible in all proportions with water, alcohol, ether, and most organic solvents. Its vapors are flammable and explosive. The physical properties of EtO are summarized in Table 1.

EtO is highly reactive; industrially, it is a primary chemical intermediate for a wide variety of compounds. The three-membered ring is opened in most of the reactions, which give a series of polyethylene glycol derivatives of increasing chain length and water solubility. Ethylene's strained configuration has been a subject of bonding and molecular structure studies. It is generally noncorrosive to metals and leaves no odor or taste residues on the materials submitted to its contact. The vapors of EtO (not the liquid form) can be flammable and explosive at concentrations above 3% in air. For this reason, it is often combined in sterilant mixtures with an inert gas to eliminate flammability.

EtO is used outside the health care industry as well. Actually, only a small fraction of EtO is used as a sterilant. It is registered as a pesticide by the Environmental Protection Agency (EPA) and is widely used as a fumigant in the food industry. It is also used as a chemical in the manufacture of detergents, plastics, fibers, film, antifreeze, and other products.^[10]

MECHANISM OF ETHYLENE OXIDE STERILIZATION

The activity of EtO, similar to many other disinfectants, preservative, and sterilizing agents, such as formaldehyde, beta-propiolactone, methylbromide, and ethylenimine, depends on an alkylation reaction.^[9] This reaction occurs with some groups within the complex enzymes, proteins, and nucleic acids in the bacterial cell.^[11] These compounds can then no longer be effective or necessary to the vital processes of the microorganism cell. Furthermore, one would expect these effects to vary according to the extensions of reactions: static, mutagenic, or toxic.

The effects of EtO concentration and process temperature were widely studied.^[8,12,13] Ernst and Shull^[13] initially verified that the lethality kinetics of *Bacillus subtilis* var. niger spores is of zero order at high levels of EtO. With the EtO concentration reduction, the reaction becomes first order. Its sterilization curves at different temperatures show the required EtO concentration, and the duplication of the reaction rate of every 10°C .

It has been well established that microorganisms that have been equilibrated with atmospheric humidity—or even dried to very low humidity, however, retaining some free water—are killed easier than those desiccated. It is accepted that organic chemical reactions occur through an activated complex formation; thus, we can infer that water influences this activation. Water must also be present as a reaction medium or solvent if biological entities are to be ionized, so that they can enter a transition state with EtO.^[14] Furthermore, no sterilizing activity can be observed when a nonpolar solvent such as dioxane and chloroform replaces water.

**Table 1** Typical physical and chemical properties of ethylene oxide

Molecular weight	44.05
Specific gravity ($H_2O = 1$) at 68°/39.2°F (20°/4°C)	0.8700
Specific gravity (air = 1)	1.49
Vapor pressure at 68°F (20°C)	22 psia (151.7 kPa abs)
Solubility in water	Complete
Percent volatile by volume	100.0
Evaporation rate (butyl acetate = 1)	High
Boiling point at 1 atm	50.9°F (10.5°C)
Freezing point at 1 atm	− 170.7°F (− 112.6°C)
Appearance, odor, and state	Colorless liquid and gas at normal temperature and pressure. Nonresidual, ether-like odor about 500 ppm. Odor not detectable until well above the PEL. Shipped and stored under nitrogen pressure as a liquid

Water has another function in this sterilization process—the sterilizing agent concentration on the surface of the microorganism. One can visualize microorganisms in an EtO environment in which all the sterilant is in the vapor phase, and in which the reaction rate is dependent on both the number of collisions of EtO molecules with active sites of the organism, and the colliding molecules absorption by the organism, followed by migration of the EtO molecules to the active sites. The collision reaction is quite slow; however, in an atmosphere containing water vapor and EtO, water will equilibrate the organism in the liquid phase, dissolve the EtO, and concentrate the EtO on the organism as a solution, thereby increasing the rate of microorganism killing.^[14]

TECHNOLOGY OVERVIEWS

Occupational Engineering Considerations

Hazard assessment of EtO has involved considerations about its chemical composition, characteristics, and reactivity. In spite of EtO's readiness to be transformed in the body to ethylene glycol and ethylene chlorohydrine, and its biological half-life of about 10 min, it is distributed throughout most body organs. Studies with cells, animals, and also epidemiological ones, showed that EtO is able to produce neuropharmacologic, neurotoxic, reproductive, teratogenic, and mutagenic effects.^[15–17]

The Occupational Safety and Health Administration (OSHA) is responsible for regulating the in-plant occupational exposure to EtO in the United States. Under the current OSHA standard, accepted by several other countries, the permissible exposure level (PEL) of EtO is 1 ppm (1.8 mg m^{-3}) per 8 hr (time-weighted

average). However, an action level of 0.5 ppm is advisable, since it is a guarantee of employers from low employee exposure levels.

The OSHA has also established an exclusion limit for EtO of 5 ppm (9.0 mg m^{-3}) average over a maximum sampling period of 15 min. In addition to these regulatory pressures, high levels of concern about workers protection and the potential liability implications have significantly increased industry's interest in control measures for EtO.

The main EtO sources that potentially contribute to workers' exposure in sterilization plants generally can be divided into four major categories.^[18]

- Exposures associated with sterilization equipment operation: sterilizer (door gasket leaks, piping leaks, leaks from valves and fittings, vent line leaks, and plume recirculation); vacuum pump (seal leaks, degassing from sealant discharged to drain); sterilant gas storage and delivery system, such as tanks, cylinders, or drums (leaks from valves and fittings, gas line leaks, and releases during change over).
- Exposures associated with sterilized product degassing: unloading, transfer, storage, and spore sample removal.
- Exposures associated with maintenance operations: routine maintenance and repair, preventive maintenance.
- Exposures associated with emergency situations: major leaks, major spills, and equipment malfunctions.

Engineering solutions must be studied, developed, and introduced in order to eliminate or, at least, minimize problems in all the steps.^[19]

Sterilization by Ethylene Oxide

3

Ventilation

General area ventilation systems are designed on the basis of how much EtO can be degassed into the specific area mentioned. It is essential to consider the total quantity of EtO remaining in the product after sterilization. This will include packaging EtO in the cardboard vapor spaces and the primary packaging, as well as the absorbed/adsorbed EtO in cardboard, the packaging, the product, and the pallets.

Vacuum pump modifications

Vacuum pump modifications usually involve conversion of a once-through liquid ring pump to a full sealant recovery pump. This will eliminate any continuous liquid discharge to the drain. The sealant can either be water or oil. The use of water places limitations on the maximum vacuum depth, which is reasonably attenuated because of the vapor pressure effects. The use of oil eliminates this maximum vacuum depth limitation.

Hot degassing

The major source of worker exposure to EtO in the plant is the degassing operation after removal from the sterilizer. Different types of products absorb or entrap EtO at different levels, depending upon the nature of the product, its specific materials of construction, how it is packaged, and the specific sterilization cycle to which it was exposed. Unfortunately, not all the absorbed or entrapped EtO is

removed in the sterilizer post-evacuation cycle. Hence, the remaining EtO will degas after the products are removed from the sterilizer. This degassing process typically takes place over an extended period of time (days) at typical plant ambient conditions and usually it is necessary that the products be quarantined for this period.

The use of heat in hot degassing chambers or rooms to accelerate the EtO degassing has been known for a long time. A hot degassing tunnel built directly behind the sterilizer has also been used. In this case, the sterilizer must have double doors and one must provide automatically taking out the pallets from the sterilizer and transporting them into the tunnel.

Automated systems

The most efficient way to protect the worker is keep him away from all operations, like loading, unloading, and starting procedures during the cycle. So the sterilization process should be automated and computerized.^[20] Besides the worker protection, the computerized system allows the cycles “self-certification,” which adds reproducibility advantages to efficiency of the sterilization cycle.

Fig. 1 (derivada do 6, mas modificada) shows a plant design that exempts the worker presence, except near the control panel. The residue monitoring should be included in the system. It must embrace the environment and obviously all processed products and discharges. Among several options, gas chromatography, especially the one with head space, has been the most adjusted.

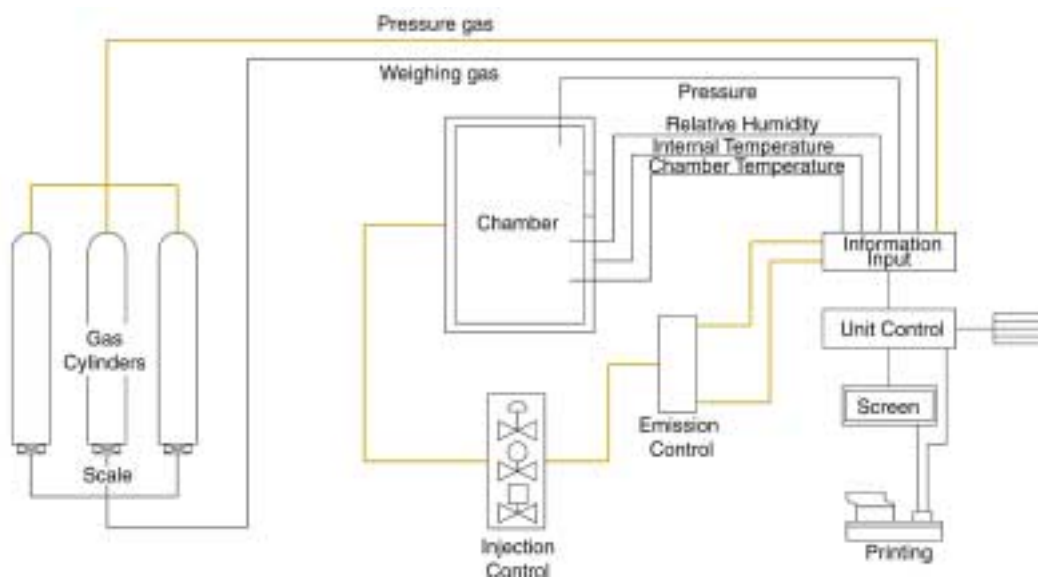

Fig. 1 Example of a sterilization plant provided with automatic system.

Ethylene Oxide Emission Control

During the handling of the ambient controls, the different forms of EtO emission must be controlled, in order to minimize indirect contamination to the population. For example, according to the amendment of the TA-Luft (German air pollution regulations) in 1986, the emission limit of EtO has been fixed to a concentration of $5 \text{ mg N}^{-1} \text{ m}^{-3}$ at a mass flow $> 25 \text{ g hr}^{-1}$. Mayer et al.^[21] described an appropriate plant of compact design that, using installations for ethylene glycol reactions, ensures these limiting values for the sterilization with EtO.

There are current technologies that can be used to control EtO emissions to the environment, with specific advantages and disadvantages.^[22]

Water scrubbing

This technology involves the absorption of EtO into water in a packed column. The gas stream discharged from the sterilizer enters the column near the bottom and flows upward through the packing material. There are systems in which absorption of gaseous EtO into the aqueous solution occurs, with its posterior reaction with water to form ethylene glycol, promoting cooling and recycling of the solution for further EtO removal. The use of an acid reaction (0.1 N is a good concentration, see Fig. 2) with water is a good option; anyway, it will be necessary to neutralize water, before its discharge to the environment (usually once or twice a year).

Thermal incineration

Thermal incineration uses a flame to oxidize EtO to carbon dioxide and water at high temperature (typically

760–982°C or 1400–1800°F). A residence time of 0.3 sec–0.5 sec is enough to achieve a high EtO destruction efficiency.

Difficulties are related to the high cost of the equipment and to limitations in the case of mixtures, when hydrogen chloride (HCl) and hydrogen fluoride (HF) are involved.

Catalytic oxidation

In a catalytic oxidation system, the gas stream exhausted from the sterilization is first diluted with relatively large quantities of air and heated up to a considerably lower temperature (204–426°C or 400–800°F). The mixture is then passed through a catalyst bed where EtO is heated with oxygen and converted to carbon dioxide and water.

Even with the advantage of high EtO oxidation efficiency, there are limitations related to potential decomposition of mixture compounds in toxic by-products (such as phosgene). In addition, the equipment cost is relatively high.

TECHNOLOGY NEW TRENDS

Related to explosive decomposition properties of EtO, pure liquid EtO can inflame in the presence of an ignition source.^[23,24] The precise threshold limits for liquid decomposition are influenced to some extent by the type of ignition source, as well as by the geometry of the vessel used. Pure EtO vapor can explode by decomposition in the presence of common igniters. Pure EtO vapor at normal storage conditions is more difficult to ignite than mixtures of EtO and air or mixtures of hydrocarbons and air. The potential for decomposition can be eliminated by diluting EtO vapor with a specified proportion of inert gas.

Though EtO itself may be used to carry out the sterilization, since the beginning of its use as a sterilant,

Fig. 2 Reaction time to form ethylene glycol considering time.

Sterilization by Ethylene Oxide

5

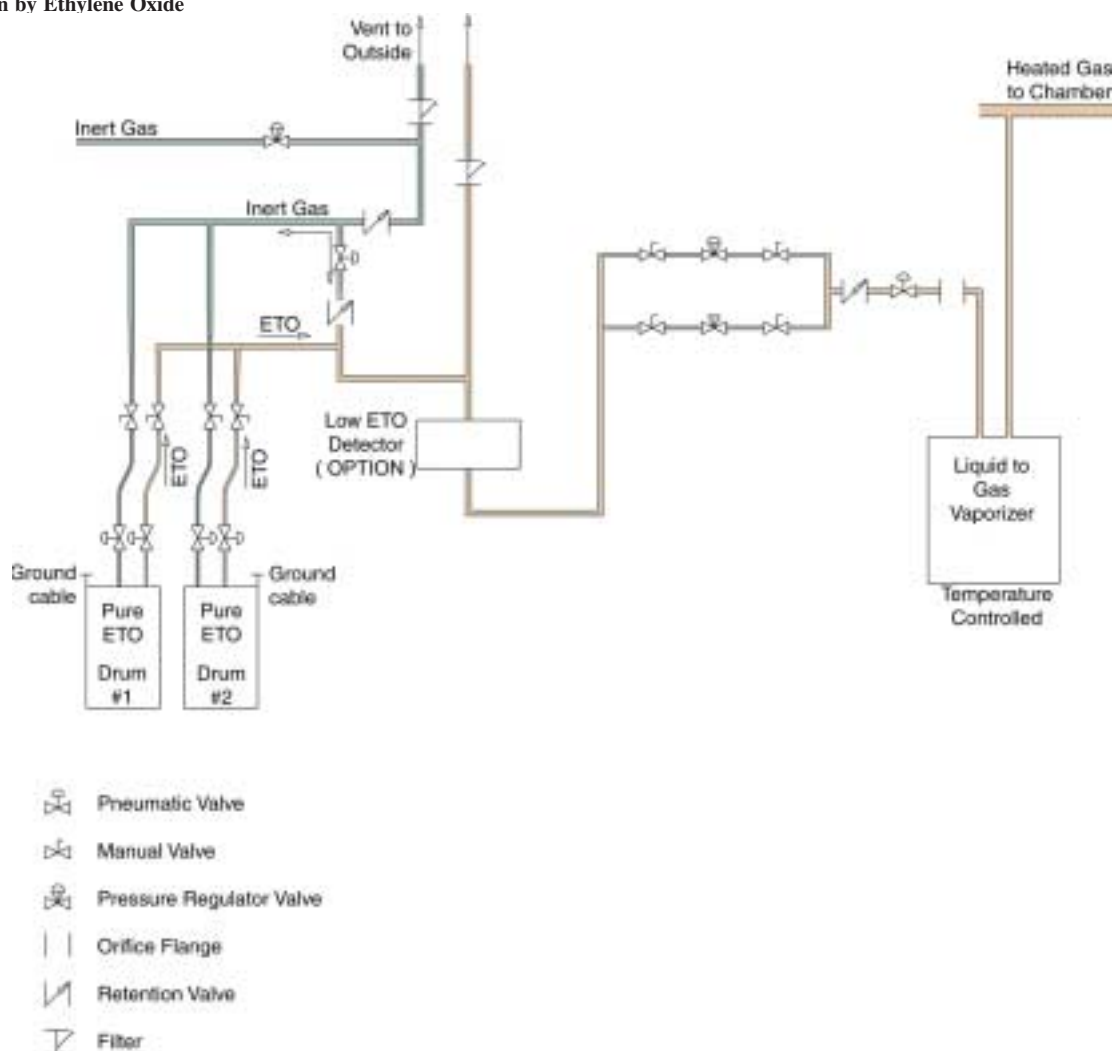

Fig. 3 Example of a single installation for a 100% EtO sterilization system.

this has not been done. Instead, EtO sterilant has been most used in a mixture with a flame retardant. Over the 1970s and 1980s, dichlorodifluoromethane, known in the industry as CFC 12, was the flame retardant of choice for use with EtO in a sterilant mixture. The most commonly used mixture consisted of 27.3 mol% (12 wt%) EtO and 72.7 mol% (88 wt%) CFC 12; this mixture is commonly referred to 12-88 in the industry. Also, a 10:90 mixture of EtO: carbon dioxide (CO₂) was used, but requiring an increasing of 15 psig in the sterilization pressure (this mixture contains only 10% EtO in volume, in contrast to 27% in volume of the 12:88 mixture).^[10]

Due to problems that have arisen with the use of CFC12 (one of the compounds which causes significant damage to the ozone layer in the upper atmosphere), worldwide reduction and elimination of CFC12-use have been started up. This restriction, although related to inert dilutor and not to EtO, reached great part of the users being thus added to the occupational limits requirements. The new

technician-scientific concepts reached the economic area^[25] aggravating extensive fetching of alternatives.

Alternatives that had gained new impulse were the mixtures with carbon dioxide. The 30:70 mixture with inflammability features has led to the construction of new plants, considering the requirements.

Another option is a nonflammable EtO—carbon dioxide mixture that contains less than 40% of the EtO per unit volume, as does 12-88. Thus, sterilization must be carried out either at higher pressures as for longer exposition times. Furthermore, the large difference in the vapor pressures of EtO and carbon dioxide causes the mixture to separate upon withdrawal from the storage tank or cylinder, raising the danger of delivering a sterilant mixture rich in carbon dioxide, which will not sterilize, or rich in EtO, which is explosive.

Several companies also re-evaluated their positions about using 100% EtO.^[25] In fact, the high costs to build an explosion-proof equipment with adequate installations

would be paid back in savings by switching to 100% EtO. Also, in the past, the main difference between sterilization with 100% EtO and 12/88 was that a deep vacuum was generally used for 100% EtO sterilization, so that all of the air in the package was sucked out, then replaced with a mixture of EtO and moisture; this deep intense vacuum required breathable packaging material or vents that would allow the air inside to escape, so the package would not blow up like a balloon and break. A vacuum was generally maintained in the 100% EtO sterilizer, so that if any leaks occurred, outside air would be sucked into the sterilizer, rather than EtO would leak out, as can occur with positive sterilizer pressures.

Nowadays, it is known how to use 100% EtO along with an inert gas like nitrogen to get safe sterilization, even for the most sensitive packaging. Pressures may be balanced and a modern computer that controls 100% EtO sterilizer is a very versatile piece of equipment. Fig. 3 shows schematic installations with an inert gas hookup to the drum. There are also two devices to make sure that the EtO supply to the sterilizer is shut off when the drum is emptied. One is the weight scale, which automatically signals the computer when a preset amount of EtO has been withdrawn and shuts off the drum by a compressed air valve. The another device is the computer that stops the flow when it senses a change from EtO to the inert gas.

Without these two devices, it is possible that the drum could be filled with inert gas and, of course, this would not sterilize the materials.

Of course, there are no electrical switches or an ignition source in the closed sterilizer–heat exchanger system. Even the presence of high amounts of moisture both in the product from the preconditioning rooms and from the humidity injection system would reduce the likelihood of an explosion by absorbing the EtO into the moisture and by eliminating the cause of static charges.

If inert gas lines are hooked into the EtO pipes near the EtO source, inert gas can sweep the EtO from the lines so that they will be either filled with the inert gas or be empty. Inverting the filters and flushing the lines with inert gas can keep any EtO from being collected in the filter housing—that also eliminates the exposure involved in changing filters. Filter changing is probably the major source of exposure for all types of EtO sterilization and this system virtually eliminates that problem.^[22]

The use of 100% EtO sterilization techniques offers low residuals due to the more efficient EtO removal from the package by the deep vacuum. The process of “pulsing” the vacuum as reported by Christensen^[26] not only greatly lowers residuals which form glycols and chlorohydrins by quickly reducing the amount of EtO in the package, but also allows degassing outside the sterilizer to be done

Fig. 4 A typical sterilization cycle observed with single-use 100% EtO cartridges.

Sterilization by Ethylene Oxide

7

within the OSHA limits. In fact, one of the latest trends is to do all the degassing in the sterilizer, so OSHA exposure levels are never even approached. This procedure is ideal for 100% EtO systems, especially those having an EtO disposal unit (Fig. 4).

Recent knowledge about ozone-depleting gases and an international consensus on the need of reducing their effects promoted a search for alternative chemicals to several different CFC applications. From these, one of the most interesting are the hydrochlorofluorocarbons (HCFCs) which, besides being similar to CFC in inhibition of explosiveness and inflammability of EtO, can also be used as transitional compounds while more environmentally suitable compounds are not available. An EtO–HCFC (10:90) mixture was compared to 100% ethylene sterilizing gas to determine its relative ability to kill seven different bacteria. Results demonstrated that the EtO–HCFC mixture was equivalent to the 100% EtO sterilant to kill vegetative organisms, as well as spore suspensions in

the absence of serum and salt, and better with these contaminants on carriers.^[27] Also, a study performed^[28] to compare sterilization effects between Oxyfume[®] 12 (using EtO and CFC12, 12:88) and Oxyfume 2002 (using EtO and HCFC 22 and 124, 10:63:27), under different concentrations (450 mg L^{-1} and 600 mg L^{-1}) and different temperatures (45, 55, and 65°C) revealed similar results, even in different concentrations (similar D value using *Bacillus subtilis*, var. *niger*, ATCC 9372).

Additional advantages of this new mixture are related to the use of the same equipment and installations previously developed for the CFC mixture (Fig. 5), with only a little increase in pressure or time of exposition, during the sterilization cycle. The only concern is that, at present, HCFC is targeted to be phased out by the year 2020 in Canada (2 in 9) and 2030 in the United States (3 in 9).

Different options can require other kinds of equipment, designed with the goal of protecting the workers, environmental preservation and safety of products.

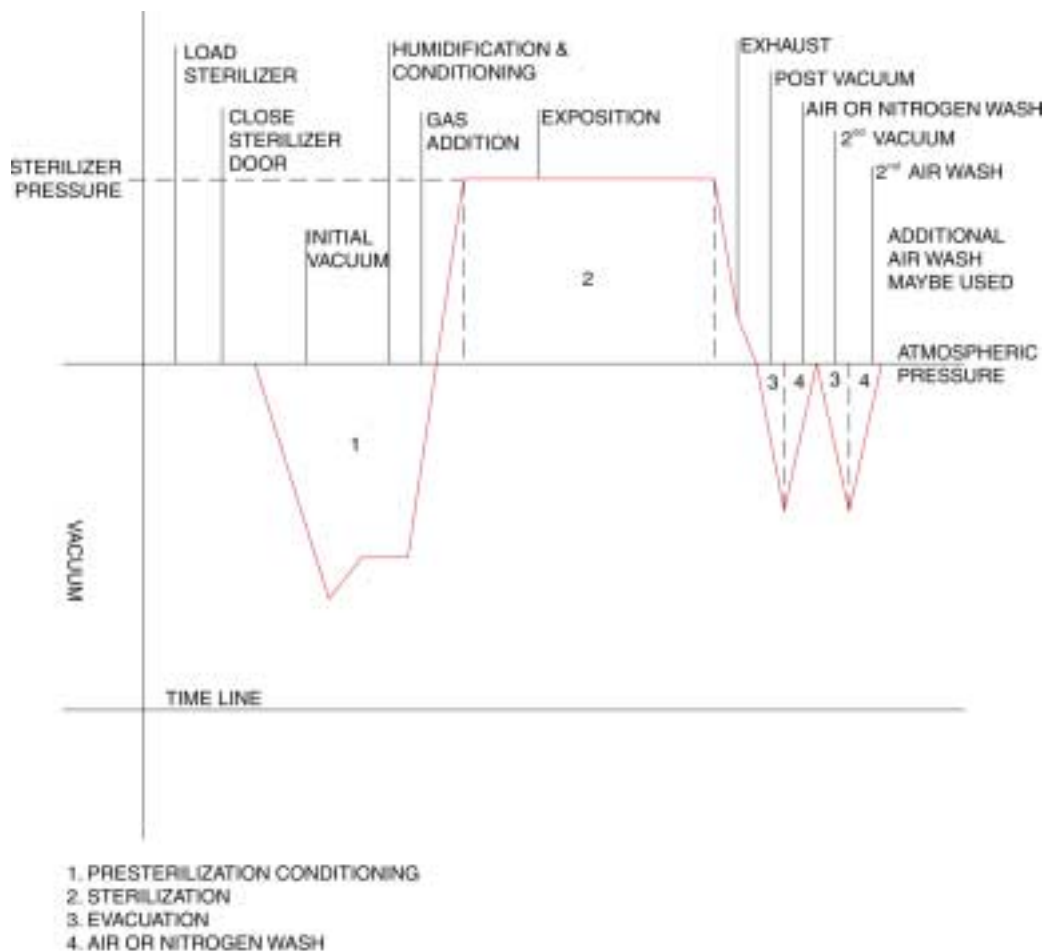

Fig. 5 Typical sterilization cycle with CFC–EtO and HCFC–EtO mixtures.

Validation and Routine Control of Ethylene Oxide Sterilization

Even though the definition of sterility is an absolute condition, the effectiveness of the sterilization process can be determined by measuring the reduction of microbial population. Such measurements reveal the kinetics of microbial inactivation, and it is from the exponential nature of inactivation that the concept of sterility assurance level (SAL) is derived. This value is expressed as a negative power to the base 10. SALs of both 10^{-3} and 10^{-6} have been adopted worldwide. However, there is a tendency to adopt a single standard, 10^{-6} .^[29]

The validation of a sterilization process is a documented procedure, which obtains records and interprets the data required, to show that a process will consistently comply with predetermined specification. Besides respecting the SAL, the biocompatibility and functional properties of a product have to be respected.

The most important current standard is ANSI/AAMI/ISSO 11135—1994 (revision of ANSI/AAMI ST27—1988). Medical devices validation and routine control of EtO sterilization were approved by the Association for the Advancement of Medical Instrumentation (AAMI), the American National Standards Institute, Inc., (ANSI) and the International Organization for Standardization (ISO). This standard considers the following steps for validation: commissioning and performance qualification, which includes physical and microbiological qualification. Medical devices to be sterilized shall be manufactured under conditions that ensure that their bioburden is consistently low. Another important point is about the AAMI specification that the biological indicator evaluator resistometer (BIER) is the appropriate vessel for evaluating resistivity to sterilization of biological indicators.^[30,31]

The adoption of the validation standard document reflects the medical industry ongoing commitment to safety, efficacy, and global harmonization of manufacturing standards. Its purpose is to provide confidence in all markets that the sterilization process is properly designed, tested, and monitored.^[29]

According to the standard, the sterilization process using EtO shall include preconditioning and/or conditioning, sterilization cycle, and aeration. Preconditioning and/or conditioning treatments must be performed under controlled conditions for a defined period of time to achieve specified temperature and relative humidity within the load. The sterilization cycle includes: air removal, conditioning (if used), sterilant injection, maintenance of specified conditions for the exposure time, sterilant removal, flushing (if used), and air admission to atmospheric pressure. Aeration must be performed with product retained under specified conditions, in the sterilizer and/or in a separate chamber or room. One of

the most important differences is that ISO 11135 requires additional temperature and humidity monitoring of the load, both during validation and routine.^[32]

According to the ISO standard, the temperature and humidity of the load must be measured during the performance qualification. These measurements should be used to establish range specifications for the temperature and humidity of the product at the end of both the preconditioning and conditioning steps, before adding the sterilant into the chamber. Only in an Annex of ISO standard (B), included as a guidance, at the end of preconditioning, the measured temperature and humidity ranges within the sterilization load should not exceed $\pm 5^{\circ}\text{C}$ and $\pm 15\%$ humidity. This annex also contains the information that a recorded temperature range within an empty chamber during sterilant exposure of less than or equal to $\pm 3^{\circ}\text{C}$ of the required set point should be obtained.

Throughout the exposure time, the sterilization load should attain the minimum specified temperature and the temperature range across the product load should be less than or equal to 10°C at any given time during sterilant exposure. The actual temperature should be determined during physical performance qualification. Although temperature measurements have long been required, direct humidity measurement of the load has not. Manufacturers have used vapor pressure calculations to ensure that when steam is added to the chamber after initial evacuation, the resulting increase in pressure indicates attainment of a level of humidity appropriate to support microbial inactivation.

By interrupting the sterilization cycle just before the introduction of EtO gas, validation runs can be performed using currently available chamber humidity sensors, even though, care maintenance and calibration of these sensors are very important, and a real challenge is to improve their state-of-art.

A double check for EtO concentration is required during sterilization (weight of sterilant, volume on direct analyses, besides the pressure rise). During aeration, the temperature of the load must be monitored in reference to a specified range established. The microbiological performance qualification should demonstrate the adequacy of the process to the sterilization of the product by the inactivation of indicators for EtO sterilization. The bioburden of the product has to be established, and indicators for EtO sterilization—spores of *B. subtilis* var. niger, which are being considered for another classification as *B. atrophaeus* on the basis of high DNA–DNA reassociation values and confirmatory automated Ribo-Print analysis^[33] must comply with EN 866-2. These indicators shall be placed at representative positions throughout the sterilization load under the cycle conditions selected to deliver less lethality. The indicator should represent, considering the holder where the spores are

inoculated, the load configuration and the package that protects it in the worst sterilizer conditions. This is added to the worst conditions in the configuration of the load.^[10,34]

According to the standard, the microbiological qualification can be performed by the lethality determination of the cycle by three methods. In one of them, the lethality shall be determined by the construction of a survivor curve using direct enumeration of a survivor. At least five points employing graded exposure times to EtO, with all other process parameters remaining constant, except time, shall be included on the survivor curve. The second possibility is the fraction-negative method, in which indicators for EtO sterilization are also exposed to EtO in graded exposure times with all process parameters remaining constant, except time. After exposure, the indicators for EtO sterilization shall be tested by direct immersion in an appropriate culture medium. Both methods permit calculation of D value (Fig. 6).^[35] The method C, or half-cycle method, can be used only for conventional product release. It involves the determination of the minimum time of exposure to EtO at which there are no survivors, with all other process parameters,^[21] except time remaining constant. Two further experiments should be performed to confirm the minimum time. Both should show no growth from biological indicators. The specified exposure time should at least double this minimum time.

Considering the parametric process, it requires more attention in comparison with conventional release. In this case, a secondary measure of chamber temperature is required, and the chamber humidity and gas concentration

must be directly monitored, what constitutes an important challenge, mainly related to safety in 100% EtO cycles (Norma ISO). An inherent characteristic of the sterilization process that reduces the interest in obtaining conditions that allow the parametric liberation is related to the attendance to specified limits of EtO, ethylene glycol and ethylene chlorohydrine previously to the product release, what demands additional time.^[36]

Another possibility, proposed by Rodriguez et al.,^[37] considers the concept of accumulated lethality (Fo), used for thermal sterilization, but applied to optimization of EtO sterilization technology. A mathematical model of the inactivation of biological indicators spores by EtO was developed, along with two formulas: a “response” equation for calculating the number of survivors of a sterilization cycle, and a formula for determining the accumulated lethality of exposure to EtO. Experiments verified that the equations are applicable to processes with relative humidity values between 15% and 90%, enabling users to compare the lethality of dissimilar EtO cycles.

On completion of the validation programme, the test results should be compiled into a test report, and characterize the certification of validation.

OUTLOOK

Despite the serious criticisms against EtO related to toxicity and environmental aspects, sterilization using this gas, 100% or in various compositions, is one of the most

Fig. 6 Microbial death rate (D determination using direct enumeration of survivors) for *B. Subtilis* var. *niger* on paper (D = 4310 min), aluminium (D = 6143 min), and plastic (D = 12,300 min) carrier.

widely used processes. Compared to alternative processes, EtO still remains a suitable choice than irradiation, because it promotes molecular alterations in different polymeric compounds, and it also causes long-term problems with the ramrods of ^{60}Co , when its active life expires. Besides that, the irradiation with difficulties persists with accelerated electrons, in spite of the obtained improvements.

Furthermore, the EtO process presents wide effectiveness and possibility of validation in industrial sterilizers, when compared to the plasma sterilization process. It also shows advantages in comparison to other sterilant gases (formaldehyde and hydrogen peroxide) related to permeability, diffusion, volatilization, polymerization, and compatibility.

So, since there is not a perfect sterilant agent, we can consider the EtO process as ideal, although it demands a certain amount of knowledge for its safe and effective use.

STERILIZATION BY MOIST HEAT

Dario Pistolesi

Fedegari Autoclavi S.p.A., Albuzzano, PV, Italy

INTRODUCTION

To sterilize something means to render it “aseptic” (from the Greek word *sepsis*, putrefaction, preceded by a privative *a*). In other words, it means to inactivate the micro-organisms that may produce this putrefactive action (in the broadest sense of the term).

Moist-heat sterilization is achieved when water vapor (or, more generically, moist heat, i.e., a suitable combination of temperature and humidity) at a definite temperature is introduced or generated (even indirectly) at the level of the micro-organisms to be inactivated and is maintained in such conditions for a definite time. As explained in detail hereafter, moist-heat sterilization proceeds as an inverse logarithmic progression. Therefore, only a treatment of infinite duration provides absolute certainty that all micro-organisms have been inactivated.

In pharmaceutical technology, to define an item as sterile, one must be able to demonstrate that on a statistical basis related to the processing conditions, no more than 1 in 10^6 units subjected to sterilization “may be” nonsterile. Therefore, the SAL (Sterility Assurance Level) of the product must be greater than (or equal to) 10^6 . The obvious consequence of this situation is that although the word sterile expresses an absolute concept, the word sterilized, understood as the result of an adequate sterilization process, has a probabilistic meaning.

Current pharmacopeias, standards, and guidelines related to sterilization generally use the following type of wording:

... Sterilization is a special process because its efficacy cannot be verified by simple inspection and testing on the final product.... For this reason, sterilization processes have to be validated before use, the performance of the process monitored routinely and equipment regularly maintained....

Accordingly, installation qualification and operational qualification of the sterilizer and validation of the processes, combined with continuous monitoring of each individual routine process, are now considered fundamental (1). Therefore, sterility tests (i.e., microbiological tests performed on the final product) have lost much of the

significance they had in the past (2), but they are still being performed. So-called parametric release (i.e., release based on the evaluation of tightly controlled physical parameters of each process, without performing sterility tests) is in fact theoretically accepted by many pharmacopoeias, but is (as stated, for example, in the *European Pharmacopoeia*) “... subject to the approval of the competent authorities ...,” which are generally highly reluctant to grant such approval.

All pharmacopeias consider moist-heat sterilization as the method of choice, i.e., the method to be preferred, unless, of course, the product to be sterilized is incompatible with the characteristics of steam. The reason for this preference is the fact that moist-heat sterilization provides the best combination of flexibility, reliability, and low equipment and operating costs.

OVERVIEW

Moist-heat sterilization is achieved when a suitable combination of temperature and humidity can be introduced (or indirectly generated) at the level of the micro-organisms to be inactivated. The classic way to achieve this is by means of pressurized saturated steam at the temperature of 121°C (250°F). However, other sterilizing media (e.g., superheated water or a steam–air mixture) are also frequently used to obviate certain problems that pure steam may pose. Sometimes the load is rotated inside the chamber of the sterilizer to achieve particular results.

MOIST-HEAT STERILIZATION KINETICS (3)

Consider a system contaminated by a single microbiological species (i.e., an ampoule containing an aqueous suspension of a given micro-organism) immersed in pressurized saturated steam at constant temperature. One can demonstrate experimentally that the reaction of thermal inactivation of the micro-organism develops as a first-order chemical reaction (i.e., as a chemical decomposition

reaction) in which the reaction rate is proportional at all times only to the amount of product still to be degraded. The proportionality coefficient is typical of the species and conditions of the given micro-organism. All this seems obvious for dry-heat sterilization, but not for steam sterilization, in which the water vapor molecules would appear to take part in the reaction. Actually, this bimolecular reaction is a first-order reaction, because an excess of steam is always present and its concentration can be considered constant.

The most widely used mathematical equation of the above is:

$$N = N_0 10^{-t/D} \quad (1)$$

where N_0 = initial number of micro-organisms; t = elapsed time (or sterilization time); N = number of surviving micro-organisms after exposure time t ; and D = "decimal decay time," defined as the time interval required, at a specified and constant temperature, to reduce the microbial population to 1/10 of its original quantity.

At 121°C, the D -values generally oscillate between 0.2 and 1.5 min for the various microbial species that can be encountered in pharmaceutical activity. Eq. 1 allows for two important conclusions:

1. the time required to reduce the micro-organism population to any preset value is a function of the initial concentration, and
2. the effect of sterilization in the same conditions (T and t) will be very different according to the D -value of the contaminating micro-organism.

Fig. 1 shows that the same reduction ratio is achieved for different microbial species (at the same constant

Fig. 1 Death rate curves illustrating decimal reduction concept. (From Ref. 3.)

temperature) with an exposure time that is proportional to the D -value of each species.

Consider a batch of units (e.g., a batch of filled ampoules) with a constant initial population for each unit of 100 micro-organisms or 10^2 . If $D_{121} = 1$, after 1 min at 121°C, the population will be reduced to $10^1 = 10$. After another minute, only $10^0 = 1$ micro-organism will still be surviving. After another minute, the surviving population would be $10^{-1} = 1/10$ micro-organism per unit. In biological terms, such a contamination is obviously meaningless; statistically, it means that there is a probability that $\frac{1}{10}$ of the units of the sterilized batch are still contaminated. Clearly, after another 5 min of sterilization, this probability will be reduced to $1/10^6$ or 10^{-6} . In other words, the SAL (introduced earlier) is 10^{-6} .

A more reassuring SAL, for example 10^{-9} , is very often sought. It is sufficient to extend the sterilization for just 3 additional min. The problem, therefore, is evidently not cost-related; rather, it is simply linked to the risk of subjecting the treated material to thermal degradation.

All the above considerations have been made under the assumption that the temperature is kept constant during the sterilization period. Obviously, the D -value changes when the temperature changes. When the D -values obtained experimentally for a given microbial species are plotted on a semilogarithmic chart as a function of the temperature T , a path such as the one shown in Fig. 2 is obtained.

Clearly, if D is 1.0 at 121°C, it is 0.1 at 131°C and 10 at 111°C. In other words, the value of D decreases or increases by a factor of 10 when the temperature increases

Fig. 2 Logarithm of D decreases linearly as temperature increases. (From Ref. 3.)

or decreases by 10°C. The algorithm z is defined as temperature coefficient of moist-heat sterilization, i.e., the number of degrees of sterilization temperature that causes a 10-fold variation of D or of the sterilization rate. Depending on the micro-organism being considered, the z -value varies between 5 and 15 for the 100–130°C sterilization range. The z -value is frequently assumed to be equal to 10 in the absence of precise experimental data (1).

It is evident that small temperature variations cause dramatic variations in the rate of the sterilization reaction. It is easy to calculate that a variation by only 1°C in the vicinity of 121°C causes a variation of approximately 24% in the value of D , i.e., of the sterilization rate.

F_0 or Equivalent Time

To compare the lethal effect of a sterilization performed for any given time t_x at any temperature T_x (which may vary over the time t_x), it is very useful to be able to express this lethal effect by relating it by calculation to a given reference temperature. When this reference temperature is 121°C (or, more exactly, 121.11°C, which correspond to 250°F) and z is assumed to be 10 (or 18 if the temperature is expressed in °F), the resulting algorithm is known as F_0 and is expressed by:

$$F_0 = \Delta t \sum 10^{\left(\frac{T-121}{z}\right)} \quad (2)$$

where Δt = time interval between two successive temperature measurements; T = actual sterilization temperature in °C at the time t ; and z = temperature coefficient, assumed to be equal to 10.

F_0 is known as equivalent time because its dimension is actually a time expressed in minutes. Clearly, when the values in Eq. (2) are, for example, $\Delta t = 15$ min and $T = 131^\circ\text{C}$, F_0 is 150 min, i.e., the lethal effect is 10 times higher than that of a sterilization lasting 15 min at 121°C. If instead $\Delta t = 15$ min but $T = 111^\circ\text{C}$, F_0 is equal to 1.5 min, i.e., the lethal effect is 10 times smaller than that of a 15-min sterilization at 121°C. An F_0 of 12 (delivered to the coldest point of the load) is generally considered sufficient for adequate sterilization in the pharmaceutical field (4).

MOIST-HEAT STERILIZATION PROCESSES

Current pharmaceutical production practice uses substantially three moist-heat sterilization processes: 1) pressurized saturated steam; 2) superheated water; and 3) steam–air mixture. Process 1 is the traditional multipurpose

process, which obviously uses pure pressurized saturated steam as sterilizing medium. Processes 2 and 3 are so-called counterpressure processes; they were introduced in pharmaceutical production practice approximately 20 years ago and, respectively, use a spray superheated water and a homogeneous mixture of steam and air as sterilizing media. These processes allow the control of the pressure of the sterilizing medium independently of its temperature (which is impossible to accomplish with pure saturated steam). As explained below, these processes are used to treat solutions in containers that cannot tolerate the internal overpressure that is generated inside when sterilized with process 1.

PRESSURIZED SATURATED STEAM METHOD

This is certainly the most widely used and most versatile moist-heat sterilization method. Accordingly, it is widely used not only for sterilization of pharmaceutical products but also for laboratory and hospital sterilization and for the treatment of medical devices. Nonetheless, it has significant limitations, especially in pharmaceutical use, which are described later. The sterilizing medium is obviously pure pressurized saturated steam. The word saturated means that the steam is in thermodynamic equilibrium with its liquid form (water) at the temperature being considered.

Typical operating conditions are 121°C (i.e., 250°F) for 15 min (or even less); this temperature is matched by a saturated steam pressure of 2.05 abs bar (i.e., 205 kPa). However, higher or lower temperatures (and, therefore, pressures) are often used, with obvious appropriate adjustments of the holding time.

The term dry saturated steam is sometimes used. It should be made clear that dryness is a theoretical condition of steam and that in practice, moist saturated steam is used. This also provides assurance that the steam really is saturated and is not superheated. The use of superheated steam may in fact cause problems in process management.

However, the steam must entrain the smallest possible amount of condensate. The term steam dryness fraction defines the amount of condensate entrained by the moist steam. A dryness fraction of 0.95 means that 100 g of moist steam consist of 95 g of dry saturated steam plus 5 g of condensate, which is (or should be) at the same temperature the steam. A dryness fraction of 0.95 is considered the lower limit of adequacy for moist-heat sterilization.

The reliability of sterilization performed by means of saturated steam is based on three essential characteristics of this medium:

1. When steam condenses, it releases heat at a constant temperature and in very large amounts; 1 kg of steam condensing at 121°C (transforming into water at 121°C) releases as much as 2200 kJ (or 525 kcal).
2. The temperatures and pressures of saturated steam have a two-way correlation. Once the steam temperature is determined, so is its pressure, and vice versa. Saturated steam at 121°C inevitably has a pressure of 2.05 abs bar; saturated steam at 3.04 abs bar inevitably has a temperature of 134°C. This entails two very interesting practical possibilities: a pure saturated steam autoclave can be equally temperature- or pressure-controlled, and regardless of the parameter used for control, the second parameter can easily be used to cross-monitor the first.
3. One gram-molecular weight of water (18 g, i.e., 18 ml in the liquid state) as steam at 121°C and 2.05 abs bar occupies a volume of approximately 15 L. This means that when steam condenses at 121°C, it shrinks in volume by almost 1000 times. Consequently, additional steam spontaneously reaches the material to be sterilized. The condensate that forms can be easily removed from the autoclave chamber by means of a condensate trap or by continuous bleeding.

Apart from these three favorable characteristics, other phenomena linked to the use of pure saturated steam must be considered:

1. To perform its microbiological inactivation action, the steam must come into contact with the micro-organisms. This can occur directly or indirectly. It occurs directly when the steam makes contact, for example, with a surgical instrument located in the autoclave chamber. It occurs indirectly when the steam is generated, for example, inside a sealed ampoule that contains an aqueous solution by heat exchange with the steam in the chamber. However, it is evident that it is impossible to steam-sterilize the inside of a closed empty ampoule or its contents if they are, for example, an anhydrous oil-based solution.
2. The air initially present in the chamber and the incondensables (generally CO₂) possibly entrained by the steam have molecular weights, and therefore densities, which are 1.5–2.0 times higher than those of steam. Therefore, at the beginning of the process, the air must be removed from the chamber, and the steam must not contain incondensables. Otherwise, they tend to stratify in the lower portions of the chamber, producing unacceptable temperature gradients.

3. When closed nondeformable containers with aqueous solutions are sterilized, the pressure inside can reach values far higher than the chamber pressure. The reasons for this are explained in detail later but, in any case, the internal overpressure can reach or exceed 1.4 bar and can be intolerable for many types of container. In such cases, it is necessary or convenient to use counterpressure autoclaves (as described later).

SATURATED STEAM AUTOCLAVES

Construction

All sterilizers intended for pharmaceutical use are currently made of class AISI 316 stainless steel, including the valves and piping. Other materials may be acceptable only for service components arranged downstream of the sterilizer (e.g., the vacuum pump or the condensate trap). The service elements arranged upstream of the sterilizer (e.g., heat exchangers or water pumps) also must be made of stainless steel.

Silicone rubber or PTFE and its derivatives are generally used for gaskets (for doors, valves, etc). The chamber of these autoclaves is horizontal, with a rectangular or (rarely) cylindrical cross-section. The dimensions of these chambers can vary considerably, from approximately 100 L to 10 m³ or more.

Doors

Doors are generally rectangular, even though the chamber is cylindrical. In this case, the doors are inscribed in the circumference. There may be one or two doors: two doors are always used when the autoclave leads into a sterile room. Two-door autoclaves are often used when this requirement does not apply, but the need is nonetheless felt to separate the loading area (where nonsterile products are placed) from the unloading area (where only already-sterilized products can be placed). The doors may be of various kinds.

Side-hinged, manually operated doors retained by radial locking bars

At present, these are the most widely used doors. The rim gasket is solid and fixed. The radial bars are moved, during closure/opening, by a central hand-wheel that is operated manually. This locking system requires lubrication, and this can entail microbiological problems, especially if the

Fig. 3 Dovetail section gasket activated by compressed air. (From Ref. 5.)

door opens onto a sterile room (the closure method that uses perimetric eye-bolts is now obsolete).

Vertically or horizontally sliding, automatically operated doors

These doors have no lubrication problems, but in the horizontally sliding version (which is common for industrial-size autoclaves), they have the drawback that they occupy a considerable amount of floor space. The gasket is generally located on the chamber rabbet and is compressed toward the door by two methods: 1) the gasket is hollow and inflatable (by means of compressed air or steam); and 2) the gasket has a particular dovetail cross-section and is contained in a slot that also has a dovetail cross-section. An adequate pressure of compressed air in the rear part of the slot is sufficient to activate the seal on the door, and the release of the pressure (without requiring vacuum) is sufficient to activate the retraction of the gasket (Fig. 3).

Diagonally moving doors

These doors combine the positive features of the two preceding types. During opening (and, in reverse, during closure), the door is automatically moved slightly upward and laterally, enough to disengage it from the mechanical systems that retain its four sides. Then the operator opens the door manually by turning it about its side hinges. The gasket is generally identical to the second one described previously.

Jacket

Saturated steam autoclaves are generally provided with a jacket, that is constituted by a second wall that more or less fully encloses the inner chamber and thus forms a secondary space around it. For the sake of brevity, the various jacket construction methods are not presented here. The purpose of a jacket is summarized as follows:

- 1) to preheat the autoclave initially and keep it warm during loading/unloading;
- 2) to preheat the load during the initial air removal phase;
- 3) to contribute to the drying of the load in the final vacuum phase;
- and 4) to reduce any condensate entrained by the steam.

Steam can be fed to the jacket-chamber assembly by:

- 1) Single feed in which the steam first enters the jacket, circulates inside it, flows out of it, and then enters the chamber. The reduction of condensate entrained by the steam can be achieved only with this single-feed approach.
- 2) Separate-feed in which, of course, two controls are provided. The jacket may be fed with plant steam, but the chamber is certainly supplied with ultraclean steam. At present, this is the solution generally used for modern autoclaves because it ensures that no microbiological or particulate contamination can reach the chamber from the jacket, which is a closed and convoluted space that is practically impossible to clean and inspect accurately.

Process

Initial air removal from the chamber

The basic reason for air removal has been addressed previously. Moreover, loads are often made of porous or packaged materials, which require reliable and rapid removal of air from the inside of the loads as well.

Today, the so-called gravity removal method is used only for special tasks. In this method, the steam enters the top part of the chamber and is distributed by a suitable sparger (theoretically on a uniform front). The air escapes through a large valve in the lower part of the chamber by way of two actions: gravity and displacement by steam. This method is rather slow and unsuitable for porous and other loads that may trap air inside recessed cavities.

A modern autoclave is generally equipped with a water-ring pump that can produce a vacuum of approximately 70 residual mbar in the chamber. Accordingly, almost 7% of the air is not removed. The following two methods are essentially used for completing air removal.

Pulsed vacuum: Once the maximum initial vacuum has been reached, the pump is stopped and steam enters the chamber until an approximate atmospheric pressure (or a higher pressure) is reached; then vacuum is produced again. Three vacuum/pressure pulses are generally sufficient to achieve suitable air removal.

Dynamic vacuum: Once the maximum initial vacuum has been reached, the vacuum pump is kept running while a 5- to 10-min. steam-injection is performed from the side of the chamber that lies opposite the vacuum drain point. Modern autoclaves can perform both methods depending on the load to be sterilized.

Heating and sterilization phases

Considerable amounts of condensate form in the chamber during the heating and sterilization phases. This condensate must be removed, and there are basically two ways to accomplish this. The first uses a condensate trap at the bottom of the chamber. This is the cheapest and simplest method, but it causes significant drops in pressure (and therefore in temperature) when the trap opens, owing to the inertia of the trap. The second method uses dynamic steam. This is the most reliable method, but it is also slightly more expensive. During the heating and sterilization phases, the vacuum pump runs continuous and extracts the condensate through a small valve. A small amount of steam of course is also extracted continuously, accordingly providing the dynamic condition of the steam.

Poststerilization phases

These phases may be very different and are clearly linked to the sterilized material and to the required results. The most common solutions are the following:

Drying-cooling final vacuum: This is produced by restarting the vacuum pump until a preset vacuum (e.g., 100 mbar) is reached. The pump is then kept running for a preset time. Porous materials (and nonporous materials also) are thus dried and cooled quickly.

Cooling by circulating cold water in the jacket: This method is used with containers that are partially filled with solutions (for example, culture media) and closed with nonhermetic closures. With such containers, drying-cooling final vacuum is not applicable because the solution would boil, and cooling by direct spray (described hereafter) may cause contamination. Steam is removed from the chamber by introducing sterile air at a pressure that is equal to, or greater than the sterilization pressure. Then cold water is circulated in the jacket. Chamber air pressurization has two purposes: to prevent boiling of the solutions and to improve heat exchanges between the load and the jacket.

Cooling by direct spraying of cold water onto the load: This method is generally used for cooling filled and sealed ampoules contained in perforated trays and generally marshaled. It is performed by spraying, or rather by nebulizing, purified water or water for injection onto the load by means of a sparger located in the ceiling of the chamber. Water nebulization produces rapid steam condensation and an equally rapid pressure drop in the chamber while the pressure inside the ampoules remains high (because the temperature of the solution decreases rather slowly). However, good-quality ampoules can withstand this treatment adequately. The water spray is generally stopped when the load temperature reaches

70–80°C. Accordingly, the load still contains enough heat energy to dry spontaneously once removed from the autoclave.

Cooling with cold water sprayed directly onto the load with air counterpressure: Very frequently, the pressure stress that occurs when using method of cooling by direct spraying of cold water, cannot be tolerated by the load. In such cases, it is possible to drain the steam from the chamber by replacing it with sterile compressed air at a pressure equal to or greater than the sterilization pressure. Cooling water is sprayed onto the load only after this replacement has been performed. However, it is obvious that this method only allows for reduction of the pressure stress of the containers in the cooling phase; the pressure stress in the sterilization phase (discussed later) is unavoidable.

Ampoule tightness tests: The purpose of these tests is to allow for rejection of ampoules that have closure defects, fractures, or cracks. These tests fall essentially into two categories: penetration of dyed solutions (usually with methylene blue) in the ampoules and poststerilization pressure stress. Details of these methods are not presented here because of space constraints.

Sterilization of the air that enters the chamber

As noted previously, in many cases it is necessary to introduce air in the sterilization chamber. This air must be sterile, otherwise it recontaminates the sterilized load or the sterile room if a two-door autoclave is connected to it. This air is generally sterilized by filtration with a system built into the autoclave. Therefore, it is necessary to:

1. Provide a filtration cartridge with suitable retention.
2. Allow in situ periodic sterilization of the assembled system by means of an automatic process of the autoclave.
3. Ensure that the filtration system and its piping maintain sterility during successive sterilization programs used for production.
4. Perform the system integrity test before and after each sterilization program of the filtration system.
5. Allow for validation of all procedures noted earlier.

Process controllers

Today, process controllers installed in autoclaves are based on programmable logic controllers (PLCs), personal computers (PCs), customized electronic solutions, or, sometimes, different combinations of the aforementioned systems. However, a very large number of autoclaves managed by old electropneumatic systems are still in operation. Modern process controllers, of course, offer previously inconceivable levels of performance. Today,

temperature and/or pressure control is generally performed with a proportional-integral-derivative algorithm. Sterilization can be time-managed or F_0 -managed (F_0 being accumulated by several flexible temperature probes enabled for this function). Some management systems offer exceptional flexibility in composing programs and setting parameters. Information provided in real time on cathode ray tube (CRT) or liquid crystal display (LCD) or produced/stored on paper/electronic media is highly detailed.

DIFFERENTIAL PRESSURE BETWEEN INSIDE/OUTSIDE OF A RIGID CONTAINER, PARTIALLY FILLED WITH WATER SOLUTION AND SEALED, DURING STEAM STERILIZATION

When a container in the conditions noted earlier is sterilized in a conventional autoclave that operates with pure saturated steam, during sterilization a considerable overpressure with respect to the pressure inside the autoclave

chamber is generated in the container. This is clearly attributable to the fact that the air (or gas) that was present at filling has remained in the container, whereas the air was eliminated from the autoclave chamber at the beginning of the process. Fig. 4 schematically explains the phenomenon in ideal conditions, i.e., considering air a perfect gas.

Experimentally, it turns out that the actual overpressure is higher than the theoretical one. This is attributable to various facts: the thermal expansion of water is greater than the thermal expansion of the glass of the container; the solution contains dissolved gases that come out of the solution as the temperature rises; air is not a perfect gas. Obviously, the overpressure depends on the filling temperature, the sterilization temperature, the ratio between solution volume and head volume, etc., but at 121°C, it is on average approximately 1.4 bar. Clearly, this phenomenon cannot be ignored: suffice it to note that the stopper of glass bottles with a mouth having a cross-section of approximately 4 cm² would be subjected to an expulsion force of approximately 6 kg.

Fig. 4 Schematic description of pressures produced inside a rigid container, partially filled with water solution and sealed, during steam sterilization at 121°C. (Adapted from Ref. 5.)

These conditions therefore prohibit the use of traditional pure saturated steam autoclaves to sterilize solutions contained in a wide variety of containers such as

1. Large-volume parenterals (LVPs) in glass bottles;
2. LVPs and small volume parenterals (SVPs) in plastic containers (flexible, semirigid, rigid);
3. Prefilled glass or plastic syringes;
4. Jars and similar containers with press-on or screw caps;
5. Blisters containing various materials, for example, disposable contact lenses.

To correctly sterilize these products, it is necessary or advisable to use a counterpressure autoclave.

COUNTERPRESSURE MOIST-HEAT STERILIZATION

Moist-heat autoclaves operating with counterpressure are sterilizers capable of controlling the pressure of their sterilizing medium independently of its temperature. They

are used essentially for the terminal sterilization of solutions.

Accordingly, a dual control principle is provided that acts independently on both parameters. Two methods currently in use are superheated water spray and steam–air mixture.

SUPERHEATED WATER SPRAY AUTOCLAVES

Fig. 5 is a typical diagram of these autoclaves. Alternatives are possible, but they do not alter the essential structure. The chamber is horizontal and generally cylindrical, with a single wall and rectangular door(s) inscribed in the circumference.

At the beginning of the process, after loading the product, the lower part of the chamber is filled with water of adequate chemical and bacteriological quality. The air contained in the chamber is not removed. A sanitary-type pump circulates the filling water through a heat exchanger (of the removable-plate or other sanitary

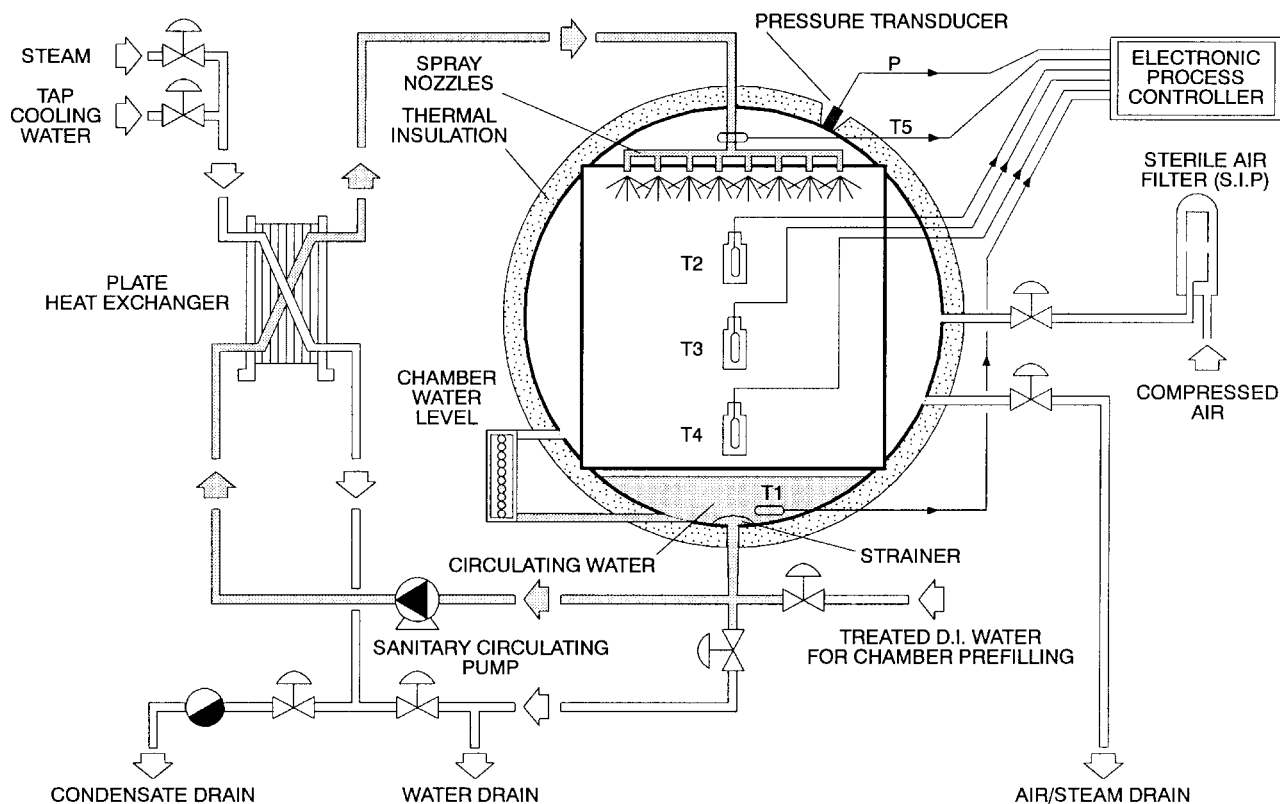

Fig. 5 Superheated water spray autoclave: simplified P.&I.D. (Adapted from Ref. 5.)

type) that is indirectly heated in countercurrent with plant steam. The water is then sprayed onto the load by a sparger located in the upper part of the chamber and equipped with a system of solid-cone spray nozzles. Uniform water redistribution in the lower layers of the load is ensured by suitable perforated racks that support the product. Sometimes additional water spray bars are located on both sides of the chamber.

Heating of the circulating water and, therefore, of the load is very gradual but quite rapid. A temperature of 121°C is typically reached in 25–30 min inside 500-ml containers; the heating rate clearly depends on the characteristics of the solution and its containers. Temperature uniformity in time and space during the sterilization phase is generally very good: much better than $\pm 1.0^\circ\text{C}$. The cooling phase is performed by the same circulating water, which is now sterile and continuously recirculated through the heat exchanger, in which cold water (instead of steam) now flows without contact with the sterile circulating water. The temperature inside 500-ml containers drops to approximately 80°C in 10–12 min.

This temperature is generally suitable to obtain rapid and spontaneous drying of the load once removed from the autoclave.

An appropriate partial pressure of air (sterilized by filtration) is maintained in the chamber during every phase of the process, to compensate for the overpressure inside the containers. Various methods for controlling the total chamber pressure (steam + air) can be used. With computerized process controllers, it is also possible to correlate at any time during each phase the air partial pressure to the average of the solution temperatures of two or more reference containers.

Consequently, the load suffers no thermal or pressure shocks because the differential pressure between the chamber and the containers can be reduced to zero or maintained at all times during the process in a direction that is suitable for the particular type of container during sterilization or, generally, during thermal treatments from 60 to 127°C.

Clearly, these autoclaves have some limitations in their application:

Fig. 6 Steam-air autoclave: simplified P.&I.D. (Adapted from Ref. 5.)

1. It is impossible, or illogical, to dry the load inside the autoclave by pulling vacuum in the chamber or by circulating warm air through the chamber and the load.
2. If materials that have upward-facing concave surfaces are sterilized, these surfaces will be filled with water at the end of the process. The obvious remedy is to load the material upside down.
3. When sterilizing solutions contained in PVC bags, so-called blushing can occur, i.e., the PVC can whiten because of water absorption. The time required for this blushing to disappear can be quite long, depending on the type of PVC and its plasticizer. Blushing does not occur with polypropylene (PP), polyethylene (PE), and poly laminated plastics.

These autoclaves are sterilizers that can vary considerable in size but are generally rather large (1–20 m³ and

more). They are often provided with automated loading/unloading systems.

STEAM–AIR MIXTURE AUTOCLAVES

Figure 6 is a typical diagram of these autoclaves; possible alternatives are addressed later. The chamber is similar to that of superheated water spray autoclaves. At the beginning of the program, steam enters the chamber directly through a suitable sparger located in the lower part of the chamber. The air initially contained in the chamber is not removed. The high-efficiency fan(s) located on the ceiling of the chamber and the flow deflector system have the task of homogenizing and circulating the steam–air mixture that forms inside the chamber. This is an important

	Superheated Water Spray = SWS	Steam–Air Mixture = SAM
Temperature uniformity in time	Good	Good
Temperature uniformity in space	Good	Good
Total pressure control	Good	Good
Counterpressure control	Good	Good
Consumption of high quality water (WFI)	Modest, for initial filling	No
Consumption of tap water for cooling	Acceptable	Approx. 3 times higher than SWS
Consumption of compressed air	Acceptable	Acceptable
Consumption of industrial steam	Acceptable	No
Consumption of ultraclean steam	No	Acceptable
Condensate recovery	Possible and easy	Not possible
Cooling water recovery	Possible, recovered water is initially very hot	Possible, recovered water is initially very hot
Autoclave price	Acceptable	Approx. 10% higher than SWS
Total process duration	Short	Approx. 30% higher than SWS
Autoclave productivity/price	High	Approx. 30% lower than SWS
Operating principle	Quite simple and straightforward	More complex than SWS
Overall machine design	Simple	More complex than SWS
Autoclave qualification/Validation	Normal	Normal
Operating flexibility according to type of load	Suitable for any kind of container with the following remarks: – upward concavities collect water – product is unloaded wet – PVC bags may generate “blushing” effect	Suitable for any kind of container: – upward concavities collect condensate only – some kind of containers may be unloaded slightly damp – limited “blushing” effect of PVC bags
Possibility of combination with saturated steam processes	Not recommended	Feasible and moderately expensive

Fig. 7 Schematic drawing of magnetically driven fan. (Adapted from Ref. 5.)

and demanding task because the air clearly tends to stratify on the bottom. The condensate that forms is removed by continuous and spontaneous bleeding from the chamber.

The cooling phase consists of feeding compressed and sterile air to the chamber to condense and replace all the steam, while maintaining the same total sterilization pressure or possibly increasing it. Cold plant water is then fed to the internal heat exchangers, which are constituted by batteries of hollow plates arranged in the two lateral sectors of the chamber (for simplicity, only one plate is shown in Fig. 6). However, this cooling method uses two solid-gas heat exchanges, which have poor efficiency. An attempt can be made to improve efficiency by increasing the air pressure in the chamber within the limits of the product, thus increasing the density of the air and therefore its exchange efficiency. The fans of course continue to run during the cooling phase as well.

Despite this refinement, the cooling phase is significantly longer than that in superheated spray water autoclaves. A mechanically critical point of steam–air autoclaves is the tightness of the fan shaft. This problem has been completely solved in the more advanced machines by adopting magnetically driven fans (Fig. 7). The air partial pressure during the program is managed as described above for superheated water spray autoclaves, and the dimensions and loading/unloading systems are also similar.

Possible alternatives to the configuration shown in Fig. 6 are 1) horizontal fans (instead of vertical fans) located on one side of the chamber. This solution entails a more severe risk of shaft bending and vibration, which can cause wear of the delicate sealing system. Moreover, it is technically more difficult to manufacture magnetically driven fans with a horizontal shaft; and 2) shell-and-tube heat exchangers (instead of plate-type exchangers).

Fig. 8 Critical comparison of superheated water spray (SWS) and steam–air mixture (SAM) autoclaves. (Adapted from Ref. 5.)

With steam–air autoclaves, blushing of PVC bags is generally less intense than with superheated water spray autoclaves and essentially affects only the areas where the bags rest on the supporting racks. Among the positive features of steam–air autoclaves is the relative ease in combining the traditional pure saturated steam cycles, i.e., in manufacturing hybrid pure steam/steam–air autoclaves (in this case, the chamber is equipped with a jacket and a vacuum pump). This combination is instead not recommended for superheated water spray autoclaves, although it is offered by some manufacturers. Figure 8 is a summary comparison of superheated water spray and steam–air autoclaves.

STERILIZING A ROTATING LOAD

Currently, the pharmaceutical market more and more often requires rotating-load sterilization autoclaves. Load rotation can have essentially three goals:

1. To maintain the stability (or homogeneity) of emulsions (or suspensions) that would tend to break out because of the sterilization temperature.
2. To sterilize heat-sensitive products at high temperature, drastically reducing the sterilization time. The logic behind this principle is that, as noted, the temperature coefficient of the moist-heat sterilization reaction is very high (z is on the average equal to 10), whereas the temperature coefficient of a classic thermal degradation reaction is much lower (on the average equal to 2). Obviously, to achieve the goal, the product heating/cooling sterilization rates must be very high and uniform. Because rotation stirs the product, it indeed facilitates the penetration/removal of heat into/from the product, especially if it is dense and viscous.
3. To provide the best possible testing of ampoule tightness with fast poststerilization vacuum. This testing method (presented above) achieves maximum effectiveness when the “open” defects of the ampoules are below the level of the solution. Ampoule rotation is the ideal method for achieving this condition regardless of the location of the defect on the ampoule (tip, shoulder, bottom).

Naturally, the production of this type of autoclave requires highly refined design and construction technology because 1) the load rotation system complicates

Fig. 9 Two superheated water spray autoclaves with a chamber capacity of approximately 4 m³, with a rotating load and sliding double doors. The man-machine interface of the process controller is not shown. The automated loading/unloading systems, frequently used with large sterilizers to allow faster loading and unloading operations, are shown instead. (Adapted from Ref. 5.)

construction significantly; 2) the loads to be rotated are generally bulky and heavy; 3) it is practically impossible to avoid mass displacements of the load during rotation; and 4) lubrication of the load bearing and rotating system must be avoided for hygiene-related reasons.

Finally, it is evident that the actual loading capacity of the chamber is reduced because of the presence of a cylindrical structure that must rotate inside it and support the load contained in appropriate trays with a lid (the entire system being appropriately perforated). Fig. 9 shows this cylindrical structure both when empty and when filled with the trays. These autoclaves are generally counterpressure sterilizers and the load is rotated throughout the process at an adjustable rate (1–10 rpm) and, if required, intermittently and in alternating directions.

STERILIZATION BY RADIATION

Stephen G. Schulman

Phillip M. Achey

University of Florida, Gainesville, Florida, U.S.A.

INTRODUCTION

The actions of ionizing radiations on matter and the subsequent interactions of the irradiated molecules are useful for the sterilization of pharmaceutical and surgical supplies. To take maximum advantage of the benefits derived from ionizing radiations, it is desirable to have an understanding of the fundamental processes that result in radiation damage to living and nonliving systems.

This article addresses with the effects of ionizing radiation on biological systems, beginning with the physical and chemical actions on condensed matter. After these sections, the biological responses of living systems, particularly microorganisms and viruses, to ionizing radiation are considered. A section on the current uses and government policies on the applications of ionizing radiation in areas important to the pharmaceutical industry is also included.

Description of Ionizing Radiation

Radiation energy can be either in the form of electromagnetic energy or of particle radiation. Radiation is distinguished as being either nonionizing or ionizing. Examples of nonionizing radiation include the ultraviolet, visible, infrared, and radiofrequency parts of the electromagnetic spectrum. These kinds of radiation are not addressed in this article.

A common feature of all ionizing radiation is that it is of sufficient energy to cause ionizations in the exposed material. These ionizations result in release of orbital electrons from atoms and cause disruptions of covalent bonds. Release of energy acquired by molecules in this manner will result in dramatic changes in the physical and chemical structures of the exposed materials because of the concentration and localized release of the ionizing radiation energy. By comparison, thermal heating is less efficient at causing bond rupture because of the wide distribution and diffuse release of thermal energy in matter. Whole-body exposure of a human to an amount of ionizing radiation energy equivalent to the amount of thermal energy received by drinking a cup of hot coffee will result

in the death of the individual within 30 days. Therefore, because of the potent biological action and the lack of our ability to sense exposure to ionizing radiation (unless the exposure dose rare is extremely high), it is important to practice extreme caution when working with this agent.

Another common characteristic of ionizing radiation is its ability to penetrate material. The two most commonly used forms for sterilization are energetic electron beams and electromagnetic radiation (e.g., γ -rays from cobalt-60 or cesium-137). The penetrating ability of γ -rays and X-rays is much greater than that of electrons. In either case, when developing protocols for using ionizing radiation in sterilization of material, the penetrating ability of the radiation must be considered.

PHYSICAL AND CHEMICAL ACTIONS OF IONIZING RADIATION

This section deals with the fundamental nature of the interactions of high-energy radiations with matter, from the absorption of the radiations to the eventual establishment of chemical equilibrium in the system. The process may be divided into three stages which are illustrated in Fig. 1.

1. The physical stage, consisting of the absorption of the radiant energy by the irradiated system. Its duration is of the order of 10^{-15} s.
2. The physicochemical stage, the processes that lead to the establishment of thermal equilibrium in the system. Its duration is of the order of 10^{-12} s.
3. This chemical stage, which entails diffusion and chemical reaction of the reactive species, ultimately resulting in chemical equilibrium. It lasts upwards of 10^{-8} s, depending on the rate constants and diffusion coefficients of the reactive species.

The Physical Stage

The absorption of the energy associated with ionizing radiation by a medium results, initially, in ionization and electronic excitation. These processes occur regardless of

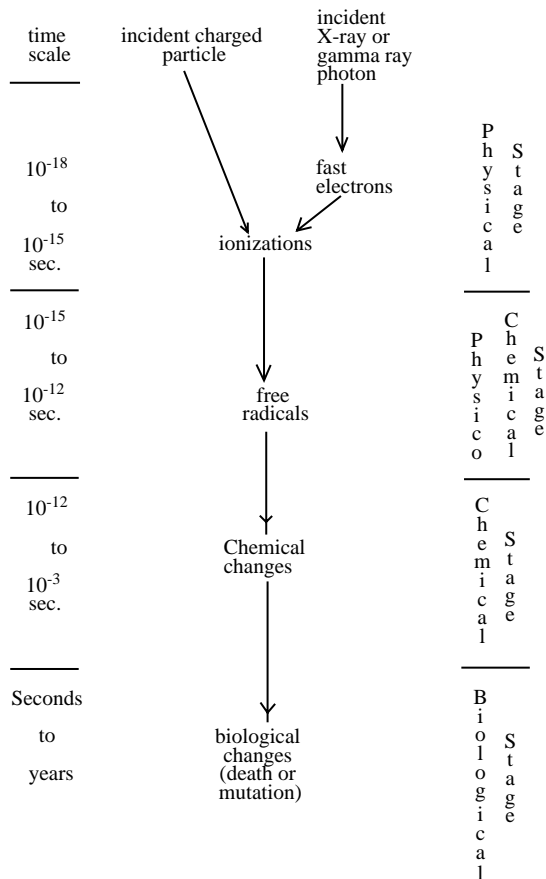

Fig. 1 The stages of radiation action on chemical systems and biological organisms.

the nature of the radiation. The mechanism of excitation and ionization by charged particles is different, however, from that effected by high-energy photons.

Charged particles

The interactions with a medium of charged particulate radiations such as protons, (β -particles, and γ -rays consist predominately of electrostatic coulomb excitation and ionization caused by ejection of atomic and molecular electrons in the medium. According to Bethe's semiclassical treatment, the energy lost to the medium, per unit length of path, by a heavy particle of charge Ze and velocity v is:

$$\frac{-dE}{dx} = \frac{4\pi Z^2 e^4 n}{mv^2} \ln \frac{2mv^2}{I} \quad (1)$$

where n is the electron density (number of electrons per unit volume) of the medium, m is the electronic mass, and I is a mean excitation potential for the medium ($I = 11.5 \text{ Zev}$

for $Z \leq 30$, $I = 8.8Z \text{ ev}$ for $Z > 30$, where Z is the mean atomic number of the medium).

The term $-dE/dx$ is called the linear energy transfer (LET) of the radiation. If electrons (β -rays) are the ionizing particles, the expression for LET is slightly different:

$$\frac{-dE}{dx} = \frac{4\pi Z^2 e^4 n}{mv^2} \ln \left(\frac{mv^2}{2I} \sqrt{\frac{e}{2}} \right) \quad (2)$$

where e is the basic of the natural logarithms.

Several important conclusions can be drawn from Eqs. 1 and 2. First, the rate of energy loss of a charged particle in a given medium is proportional to the electron in the medium. Second, because the factor v^2 outside the logarithmic term is more important than that inside, the rate of energy loss increases as the particle slows down. Third, if two particles of equal energy but different mass are compared, the heavier one will have a smaller velocity and thus a higher LET. Consequently an α -particle will produce many more excitations and ionizations per unit path length and have a shorter path length than a β -particle of the same energy.

High-energy photons

When high-energy photons such as x-rays and γ -rays pass through matter, they lose energy by way of three mechanisms: photoelectric absorption, in which the photon transfers its entire energy to an electron; Compton scattering, in which the photon transfers part of its energy to an electron; and pair production, in which the photon disappears and a high-energy electron and positron are formed. The relative importance of each of these mechanisms depends on the energy of the photon. For photons in the 100-kev to 2-MeV range, the principal mode of absorption by the medium is Compton scattering. Much higher photon energies favor pair production (at least 1.02 MeV are required to produce a pair), whereas lower energies favor photoelectric absorption. The principal effect of the absorption of high-energy photons is the production of energetic electrons that then dissipate their energies by the mechanism described by Eq. 2.

In general, the effect of transfer of energy from an energetic particle to the medium is to produce along its path a variety of electronically excited molecules, ions, and free electrons. Secondary electrons are also formed along with the ions. The electronic transitions resulting in the formation of these species occur in times [10^{-15} s] that are short compared with molecular vibration periods [$10^{-14} - 10^{-12} \text{ s}$]. The amount of energy absorbed by the irradiated system per unit mass is called the dose and is expressed in Rads, where 1 Rad ($= 6.24 \times 10^{13} \text{ eV/gm}$) is

the amount of radiation that will deposit 100 ergs of energy per gram of the irradiated system.

The Physiochemical Stage

This stage lasts about 10^{-14} – 10^{-12} s, which is typical of the period of molecular vibrations. During this period, internal molecular rearrangements can take place.

During the physiochemical stage, the excited molecules and ions dissipate their excess energy by bond rupture, luminescence, internal conversion, and energy transfer to neighboring molecules. Also during this stage, the low-energy, secondary electrons produced during the physical stage interact with molecules in the environment resulting in the formation of free radicals.

The Chemical Stage

During this stage, the reactive intermediates (ions and radicals) produced in the previous stages diffuse away from their sites of production and undergo chemical reactions with each other and with other molecules in the environment.

In condensed systems (liquids and solids), the main reactive species produced in the physiochemical stage that react in the chemical stage are free radicals. Their primary modes of reaction are atomic abstraction, radical recombination, and addition to π -bonds.

Because most systems of interest to pharmaceutical scientists are either liquids or solids, it is useful to present some of the features of radiolysis common to liquid or solid samples.

Liquid

The irradiation of liquids results initially in the ejection of electrons with the consequent formation of ions. The ejected electrons usually lose their excess kinetic energy within the electric field of the parent ion. Most of the ion pairs formed culminate in recapture of the ejected electrons, leaving the molecules in a highly excited, electronic state that may return to the ground state by internal conversion, luminescence, or energy transfer. Alternatively, the highly excited neutral molecules may split into free radicals. Some ion pairs may be sufficiently long-lived to diffuse away from the site of production and react with the surrounding medium. The free radicals are the most important reactive species formed. Once free radicals are formed along the track of an ionizing particle, they may combine with each other or they may diffuse away from the spur and react with molecules in the bulk of

the liquid medium. Those that recombine within the spur react so rapidly that they cannot be detected by physical or chemical methods. They form stable molecular products, which are known as the molecular yield. Those radicals that diffuse away from the spur and react with the medium can be detected by physical methods such as electron spin resonance spectroscopy and by chemical methods such as compound formation with radical scavengers, e.g., iodine and diphenylpicrylhydrazyl. The compounds formed by reaction with radical scavengers are called the radical yield. The mechanisms of chemical radiation effects are frequently determined by comparison of relative molecular and radical yields. The radiation chemistry of liquids has developed along two distinct paths—that of water and aqueous solutions and that of organic liquids. The radiation chemical processes responsible for the destruction of microorganisms are probably most closely related to the former, but damage to membranes and cell walls may actually be better related to the radiation chemistry of organic liquids or even some solids.

Water and Aqueous Solution

The irradiation of pure water is believed to result in two dissociative processes. The first of these is the direct dissociation of water into hydrogen atoms and hydroxyl radicals:

The second reaction is the ionization of water to yield a hydrogen ion, a hydroxyl radical, and a hydrated electron:

The hydrated electron is a powerful reducing agent and will reduce water and the hydrogen ion according to:

and the hydrogen ion according to:

Because the latter two reactions result in the same products as the direct radiolysis and because the products of reduction by the hydrogen atom and the hydrated electron are identical, it is frequently impossible to determine whether the hydrated electron or the hydrogen atom is the principal reducing species in aqueous solutions. In acid solutions, it is reasonable to assume that the hydrated electron will reduce H^+ almost exclusively and that $\text{H}\cdot$ will therefore be the predominant reducing species. However, in neutral and basic solution, the hydrated electron may be

assumed to predominate. The ultimate molecular products of the radiolysis of pure water are hydrogen gas and hydrogen peroxide, formed by the reactions:

The radiation chemistry of aqueous solutions may be considered from two points of view. The first, called the Target Theory, considers the direct effect of ionizing radiations on the solute molecules. The second approach regards transformations in the solute molecules to be attributed to interactions with the reactive intermediates formed by the radiolysis of water. Because most aqueous systems are relatively dilute, the latter approach seems statistically more reasonable. Kinetic studies of dilute aqueous systems have indeed borne out this supposition. The radiation chemistry of aqueous solutions then becomes the free radical and redox chemistry of $\text{H}\cdot$, $\text{OH}\cdot$, and e_{aq}^- .

The effectiveness of radicals in producing chemical change in aqueous systems depends on the LET of the ionizing radiation that produces these radicals. A high LET particle, such as an α -particle or a proton, will produce a large concentration of radicals along its short track. These radicals are likely to recombine, forming molecular products, before they can diffuse away from the spurs in which they are formed. Low LET particles, on the other hand, produce low radical concentration along their tracks. This minimizes the probability of recombination so that the radicals can diffuse away from the spurs and initiate chemical reactions. Protons and α -particles therefore result in high molecular yields, whereas β - and γ -rays result in high radical yields.

One of the earliest devices for the measurement of radiation dosage, the Fricke dosimeter, is based on the oxidation of the ferrous ion by OH radicals produced in the radiolysis of a dilute aqueous solution of ferrous sulfate:

The presence of dissolved oxygen alters the nature of the redox properties of irradiated water. This is a consequence of the "radical scavenging" property of oxygen. Molecular oxygen has two unpaired electrons. One of these can form a covalent bond with a hydrogen atom, forming the hydroperoxy radical ($\text{HO}_2\cdot$). This species acts principally as an oxidizing agent; e.g.:

An important consequence of this is that, whereas solutions in pure irradiated water have approximately

equal oxidizing and reducing capabilities, the presence of oxygen in these solutions can result, in some cases, in very strong oxidizing properties because of the conversion of the reducing hydrogen atom to the predominantly oxidizing hydroperoxy radical. In general, the presence of oxygen in aqueous solutions will lead to alternations of the mechanisms of radiolyses owing to the "exclusively of oxidation." Radiation damage to microorganisms tends to be far more extensive in the presence of oxygen than in its absence.

Organic Liquids

An important difference between the radiation chemistry of water and of organic liquids is that the concept of the spur (a reasonably well-defined volume in which the formation of the reactive species occurs along the track of the ionizing particle) becomes hazy. The radicals formed in water tend to recombine rather than react with the environment immediately after formation. The volume in which recombination is likely defines the spur. The radical products of irradiated organic liquids, however, are more likely to interact with their immediate environment than to undergo recombination. This is evidenced by the low molecular yields of hydrogen from irradiated organic systems.

The radiation chemistry of hydrocarbons and their derivatives has been investigated extensively. An important difference between gas phase and liquid phase radiolysis of hydrocarbons exists in that the breaking of carbon-carbon bonds is an important primary process in the gas phase, whereas in the liquid phase, the rupture of carbon-hydrogen bonds is almost exclusive. Another important difference between analogous reactions in gas and liquid phases occurs in the polymerization process. In gas phase polymerizations, the presence of radical scavengers such as iodine and benzoquinone does not appreciably alter the yields of polymeric products. In the liquid phase, however, the yields of the polymers obtained from the irradiation of materials such as vinyl chloride are seriously curtailed by the addition of radical scavengers. This indicates that polymerization in the liquid state occurs primarily by a free radical mechanism, whereas in the gaseous state, it occurs by an ionic mechanism. The irradiation of polymeric materials results in cross-linking of polymer chains and grafting of dissimilar polymeric materials. This treatment of polymers contributes considerable tensile strength and heat resistance to the irradiated polymers and is already being exploited commercially in the production of stain-resistant textiles and heat-resistant plastic containers.

Irradiation of saturated aliphatic compounds typically results in unsaturation, polymerization, and isomerization. The radiolysis of cyclohexane illustrates all three of these processes. If the radicals are very energetic, cyclohexene can be formed by the abstraction of hydrogen from a cyclohexyl radical either by a hydrogen atom or by another cyclohexyl radical. If the radicals become thermalized, recombination of radicals can occur to give bicyclohexyl. A less frequent process is rearrangement, followed by hydrogen atom capture to yield methylcyclopentane.

The irradiation of alkyl halides results in cleavage of the carbon-halogen bond. The radiolysis of methyl iodide, for example, yields ethane and molecular iodine.

Alcohols, on radiolysis in the liquid state, yield aldehydes and vicinal glycols. For example, consider the radiolysis of methanol:

and

The irradiation of frozen alcohols results in deep coloration of the alcoholic glasses. Methanol turns a brilliant purple, whereas ethanol turns blue. These colored glasses are stable if kept in the dark at low temperature. Exposure to visible or ultraviolet light results in bleaching of the alcoholic glasses as well as in the elimination of the electron spin resonance signal observed in the colored glasses. The colors are believed to be caused by the absorption spectra of trapped free radicals in the glasses. The product yields from the bleached glasses are different from those of irradiated glasses that have not been exposed to light. This suggests that the trapped radicals might be photolyzed by visible and ultraviolet light.

The irradiation of aromatic compounds results in considerably lower yields of radiolysis products than does irradiation of aliphatic compounds of similar molecular weight and functional group composition. This has been attributed to effectiveness of the delocalized π -orbitals in accommodating excitation energy without permitting the molecule to dissociate. Nevertheless, some radiolysis does occur. Benzene is known to yield biphenyl, phenylcyclohexadiene, and a polymeric material of average composition $(\text{C}_6\text{H}_7)_x$, which behaves as if it were an unsaturated hydrocarbon. Dimerization and polymer formation are also characteristic of the radiation chemistry of other aromatic hydrocarbons. The resistance of polystyrene $-(\text{C}_6\text{H}_5)_n$

to cross-linking compared with polyethylene is further evidence of the stability of aromatics to radiation effects.

Aromatic compounds frequently protect other more radiosensitive compounds from radiolysis. For example, liquid cyclohexane is protected from extensive radiolysis by the addition of a small amount of benzene. This is probably due to energy transfer from cyclohexane to benzene, followed by dissipation of the excitation energy by the aromatic π -system.

One of the most important general features of the radiation chemistry of liquids is that so much energy is deposited by the ionizing radiations, excited or reactive molecules are formed in close proximity and are likely to react with one another. This situation is not encountered in photochemistry except when lasers are used for excitation.

SOLIDS

Pharmaceutical and surgical supplies are often in the solid state when irradiated. Certainly, their containers are solid. It is therefore in order to consider some of the radiation chemistry of solids.

Because of the "fixed" positions of atoms in crystalline lattices, the effects of irradiation of solids include atomic displacements as well as electronic excitation and ionization. Although electronic alterations of materials affect their chemical behavior, atomic displacements in solids are found to have a much more pronounced effect on the physical properties of crystals. To dislodge an atom from its normal lattice position, a certain amount of energy must be transferred to the atom by an irradiating particle. Because of the large mass of the atoms, electrons and photons will be relatively ineffective in producing substantial numbers of atomic dislocations. The heavier particles, α -particles, protons, deuterons, and neutrons, will be much more effective at this process. Furthermore, unlike the primary effect of ionizing radiations in producing distal electronic disturbances through electrostatic effects, the predominant process that is required to produce atomic dislocations is direct collision.

There are two types of lattice defects that occur in all real crystals and at very high concentration in irradiated crystals. These are known as point defects and line defects. Point defects occur as the result of displacements of atoms from their normal lattice sites. The displaced atoms usually occupy sites that are not in the lattice framework; they are then known as "interstitials."

The empty lattice site left behind by the interstitial is called a vacancy. A vacancy produced by displacement of an anion or cation, along with its interstitial ion, is called a Frenkel pair, or simply a Frenkel defect. In some cases, the displaced ions are removed so far from their vacancies that they form a new layer at the crystal surface. The vacancies left behind in this case are called Schottky defects. Frenkel and Schottky defects play very important roles in the properties of solids altered by radiation damage.

Line defects (dislocations) are produced by slippage or shear of the crystal lattice. If the slippage is perpendicular to a face of the crystal so that the lattice planes on either side of the dislocation are parallel but displaced with respect to one another, the defect is called an edge dislocation. If the slippage is angular, as if produced by rotation about the shear axis so that lattice planes on either side of the defect are not perpendicular, the defect is called a screw dislocation.

There are four broad classifications of crystal types, according to the nature of the interatomic forces holding the crystal together. In metallic crystals, the atoms are thought to form a quasi-ionic lattice arrangement with the valence electrons, which bind the lattice, delocalized throughout the crystal so that they cannot be identified with any atom. Valence crystals, such as diamond, consist of a lattice in which the atoms are bonded by conventional covalent interaction throughout the lattice. This implies that a valence crystal could be considered a giant molecule. Molecular crystals (e.g., naphthalene and water) are regular arrangements of well-defined molecules that are bound together in the lattice by Van der Waals and hydrogen-bonding forces. Finally, the ultimate in electronic localization occurs in ionic crystals, in which the lattice is composed of alternating positive and negative ions held together by strong electrostatic attractions. Sodium chloride is a typical example of an ionic lattice.

Metallic Crystals

Because of the delocalization of electrons throughout the metallic crystal, no persistence of ionization or chemical decomposition can occur because a positive hole formed by an electron ejection is always refilled by an electron from the conduction band. On the other hand, sufficiently energetic radiations can cause atomic displacements. The production of interstitial atoms swells the lattice, thereby decreasing the density of the crystal.

The most obvious evidence of radiation damage in metallic crystals is decrease in electrical and thermal conductivity. This is attributable to scattering of electrons

and phonons by vacancies and interstitials that destroy the order of the lattice necessary for high conductivity.

The obvious effects of radiation damage in metallic crystals can be reversed by "annealing." Heating the irradiated materials supplies the energy required to push an interstitial back into a vacancy.

Valence Crystals

The strong bonding in valence crystals results in the failure of these crystals to demonstrate, on irradiation, quasi-chemical changes such as depolymerization. Unlike metals, however, valence crystals have no conduction electrons. This permits them to retain electronic dislocations as well as atomic displacement. The trapping of dislocated electrons in the crystal by potential wells such as those created by atomic vacancies results in coloration of the normally transparent valence crystals.

Ionic Crystals

Irradiation of ionic crystals results in atomic and electronic dislocations. The trapping of displaced electrons by anion vacancies results in the absorption of visible and near ultraviolet light, which give these crystals their characteristic colors. These pseudoatomic electrons and their vacancies are called color centers.

The exposure of colored ionic crystals to visible or ultraviolet light causes the annealing of trapped electrons and results in bleaching of the colorations induced by irradiation. In some cases in which the crystal remains uncolored upon irradiation, thermoluminescence is observed in the annealing process.

The dissolution of a heavily irradiated crystal of sodium chloride in water will result in the evolution of hydrogen and chloride from the solution. The solution also turns alkaline. This is presumably owing to the reactions of trapped holes and electrons with water:

Trapped electrons also account for the ability of irradiated sodium chloride to initiate polymerization in acrylonitrile.

Irradiation of nitrates, chlorates, perchlorates, and bromates results in the liberation of oxygen. In KClO_4 , irradiation results in explosion of the crystal due to the internal buildup of oxygen.

Molecular Crystals

The irradiation of substances that form crystals containing discrete molecules held together by dispersion forces results in radiolysis in the conventional sense. For example, the radiolysis of aliphatic carboxylic acids in the solid state yields hydrogen, carbon monoxide, and carbon dioxide. The relative yields of these gases depend on the strengths of the bonds involved in radiolysis and their frequency of occurrence. These considerations apply as well to liquids and gases and suggest no special solid-state effects.

Energy transfer in molecular crystals seems to be a well-established phenomenon. Irradiated crystals of anthracene containing only a trace of naphthacene show the characteristic green fluorescence of naphthacene rather than the violet of the primary constituent. If the material is dissolved in benzene, the anthracene fluorescence predominates.

The irradiation of ice results in formation of trapped hydrogen and hydroxyl radicals as well as the hydrated electron.

The irradiation of surface catalysts alters the properties of these catalysts through defect production on their surface. These defects have been observed to enhance and inhibit catalytic activity in specific cases. For example, the irradiation of silica gel enhances the rate of H_2 - D_2 exchange on it.

CHEMICAL PROTECTION FROM IONIZING RADIATIONS

The effects of ionizing radiations on chemical and biological systems may be minimized by the addition of certain chemical compounds to the system to be irradiated. These compounds react either directly with the radiation or, more often, with the reactive species produced by the radiations. In so doing, they are themselves transformed into other substances, but their transformation results in the preservation of the integrity of the original chemical or biological system.

At the molecular level, there are several mechanisms that account for the protection of irradiated systems by chemical agents. These are energy and charge transfer, in which an ionized or excited molecule transfers its charge or excess energy to a protecting molecule either by collision or by resonance transfer; scavenging, in which a protecting radical scavenger reacts with radicals from the initial actions of the radiation before they can attack other molecules in the system; and complex formation, in which a protective molecule can form complexes that are either

more or less susceptible to radiation damage than the original substance.

Energy and Charge Transfer

The transfer of charge or excitation energy must be fast enough to compete with dissociation processes if protection is to occur. In some cases, an activated molecule can dissociate within 10^{-14} s, the time for one molecular vibration. However, localization of energy in a particular bond usually requires 10^{-13} – 10^{-9} s. To remove energy or charge from an activated molecule effectively, the protector should have a slightly lower ionization or excitation potential. In fluid systems, the rate of charge transfer can be limited by diffusion, in which case, the donor and acceptor must be in contact. Excitation energy, however, can be exchanged radiationlessly by molecules as much as 70 Å apart by resonance energy transfer, a dipole–dipole interaction. The process is more rapid than fluorescence and competes favorably with dissociation. Transfer processes of the resonance type are extremely efficient in crystalline materials in which the high degree of order permits excitation energy to travel in excitons that transverse the crystal in a time shorter than its vibrational relaxation time. Crystalline structure also facilitates charge transfer by providing conduction bands in which electrons can freely move about.

Energy conversions within a molecule can decrease the probability of decomposition; energy can be distributed so widely that its localization in any one bond is improbable. Aromatic compounds are protective because they can probably dissipate acquired excitation energy throughout their extensively delocalized π -systems.

Scavenging Intermediates

The addition of certain compounds that react readily with free radicals can effectively prevent these products of ionizing radiations, from causing secondary damage in the system. Molecular iodine is a very effective radical scavenger forming iodo compounds with radicals and leaving behind iodine atoms to do further scavenging, e.g.:

Oxygen is a diradical that enhances radiation damage by forming radicals with other radicals. An example is the scavenging of hydrogen atoms by molecular oxygen to form the hydroperoxy radical.

Complexes

Certain compounds may exert protective action by forming molecular complexes with the original molecules of the system. These complexes might be less sensitive to radiolysis or attack by radicals, or they may be better able to transfer charge and excitation energy than the original compound. For example, the radiolytic degradation of polyisobutylene is reduced by copolymerization with styrene. The radiation resistance of the porphyrin ring is enhanced by complexing it with vanadium and other metals.

The most obvious application of chemical protection from ionizing radiations is to biological systems. For a protective agent to be biologically practical, it must be nontoxic at protective concentrations, widely distributed, and remain intact for long periods before irradiation. Many substances have been applied to this problem. To date, the most effective have been compounds such as cysteine because of the scavenging property of the $-SH$ group and the ease of oxidation of the $-NH_2$ group.

Adventitious impurities in pharmaceutical and surgical supplies may act as energy transfer acceptors, scavengers, or complexants and make radiation sterilization more difficult owing to radioprotective action.

MOLECULES OF BIOLOGICAL SIGNIFICANCE

There are two distinct theories of the actions of ionizing radiations on the compounds of living cells that result in chemical transformation that leads to mutation or cell death. The first is the target theory. This approach regards only those events that produce direct ionizations in biologically significant molecules as being important. The evidence for this is that in many cases, the amount of damage to a given organism varies logarithmically with the dose of radiation. This implies that the amount of damage possible in a cell is proportional to the number of radiosensitive molecules remaining undamaged and, therefore, capable of reacting. The other theory is based on an indirect relationship between the incident radiation and the affected, biologically significant molecules. In this approach, the solvent, water, interacts with the radiation, forming ions and radicals. These reactive species, in turn, react with the biologically significant molecules causing radiation damage. Radiation biology, under this approach, is simply a branch of the radiation chemistry of aqueous solutions. There is evidence that both the target and indirect processes occur.

In this section, the effects of ionizing radiations on molecules known to have biological significance and the

relationship of the radiation chemistry of these molecules to radiation effects observed in living organism are considered.

Carbohydrates

The irradiation of aqueous solutions of carbohydrates has the same effect as it does on alcohols. The hydroxyl groups are attacked to yield carbonyl compounds. Under anoxic conditions, dimer products and, ultimately, polymers are also formed. The primary alcohol groups of carbohydrates are especially radiosensitive. Mannitol is readily oxidized to mannose and sorbitol to glucose. Although oxidation of primary alcohol groups is favored by aerobic conditions, high yields from the oxidation of secondary alcohol groups are favored by anoxic conditions.

The irradiation of polysaccharides results predominately in their degradation. This explains why fruits and vegetables become soft on irradiation. This degradation is observed to occur both in solution and in the dry state.

Amino Acids and Peptides

The irradiation of amino acids results in transformation of both the amino and the carboxylic functions. In the dry state, glycine is decarboxylated to methylamine on irradiation; in dilute aqueous solution, however, the amino group is hydrolyzed to give glyoxylic acid, acetic acid, and formaldehyde. In solutions of concentration greater than 2%, methylamine again becomes an important product. The other amino acids are similar to glycine in their radiolytic behavior. Alanine, for example, gives ethylamine and CO_2 in the dry state and pyruvic acid and ammonia in aqueous solution.

The aromatic amino acids, when irradiated in aqueous solution, show effects that are typical of aromatic compounds and amino acids. Phenylalanine is deaminated in aerated solutions with the formation of a ketone. The aromatic ring remains relatively stable to radiolytic decomposition.

The irradiation of peptides results in a chemistry similar to that of the amino acids but also in the breakage of the peptide bond. In aqueous solution, all irradiated peptides give ammonia whether or not free amino groups are present.

The thiol and disulfide containing amino acids degrade to keto acids with the evolution of CO_2 and H_2S , when irradiated in the dry state. In solution, however, the thiol and disulfide groups are excellent radical scavengers, and free radical attack on these groups precludes deamination.

The ultimate result of irradiation of thiol-containing amino acids is their oxidation to disulfides. Thus, irradiation of an aqueous solution of cysteine results in the formation of cystine. The irradiation of the disulfides results in higher oxidation products. For example, cystine gives cystine disulfoxide in aqueous solution. Reduction of disulfides to thiols is not observed.

Proteins and Enzymes

The irradiation of proteins results in the formation of free radicals at the sites of $-S-S-$ bonds. Aromatic amino acids in the proteins are also particularly susceptible to radiolysis; decarboxylation and deamination being common results of irradiation. Rupture of the peptide linkage is characteristic of the radiolysis of proteins. In the case of enzymes, the destruction of peptide linkages is accompanied by a decrease in biological activity. This decrease continues after irradiation is stopped. The mechanisms of radiolysis in the dry state and in solution are different, but the results are usually similar. One of the more important differences between these results is the degradation of proteins by dry-state irradiation compared with increase of molecular weight through cross-linking in solution. In general, the radiation chemistry of proteins and enzymes may be considered a special case of the radiation chemistry of peptides and amino acids.

Respiratory Proteins, Vitamins, and Coenzymes

Respiratory proteins

These substances are iron, porphyrin, protein complexes. Irradiation of these substances may produce effects in the porphyrin ring or in the protein, but oxidation or reduction of the iron is almost always involved. The iron in ferricytochrome-c is reduced to the ferrous state under neutral conditions. Under acid conditions, the ferric form is favored. Hemoglobin and oxhemoglobin are both oxidized from the ferrous to the ferric state, destroying the property of oxygen transport. Large radiation doses result in attack on the porphyrin ring and denaturation of the protein. When irradiated in the dry state in the absence of oxygen, hemoglobin is not oxidized, but it becomes insoluble because of protein denaturation. Myoglobin behaves in a manner similar to that of hemoglobin but is considerably more radiosensitive. Myoglobin is a copper-containing respiratory protein of molecular weight more than 10 times that of hemoglobin. In this case, attack at the protein part of the molecule predominates.

Vitamins and coenzymes

The irradiation of coenzyme I (diphosphopyridine nucleotide) results in reduction of the pyridine-carbox-amido ring. The product of this reduction is probably a dimer that is itself radiosensitive.

The B group vitamins, thiamine and riboflavin, are destroyed on irradiation in dilute aqueous solutions. Riboflavin is reduced in air-free solutions to a semiquinone form. Nicotinic acid is decarboxylated on irradiation in air-saturated aqueous solutions.

Para-aminobenzoic acid is destroyed on irradiation in aqueous solution by deamination and decarboxylation. Sulfanilamide and sulfathiazole are inactivated presumably because of deamination. The cobalt in vitamin B₁₂ is reduced on irradiation from +3 to the +2 state.

The plant hormone auxin has been shown to be radiosensitive. The product of the irradiation of auxin (β -indoleacetic acid) is a polymer similar to that obtained in the radiolysis of indole.

Nucleic Acids

The nucleic acids DNA and RNA are responsible for the transmission of genetic information and protein synthesis. Both of these processes are dependent on the ordering of purine and pyrimidine bases that are bound to the main body of the molecule by phosphoric ester linkages. The main body of these molecules consists of ribose (5-carbon sugar) molecules linked together by phosphoric acid units to form a long strand. The purine and pyrimidine bases branch off from the chain at the ribose sites. The DNA molecule consists of two helically intertwined strands of nucleic acid held together by hydrogen bonding between purine pyrimidine pairs on opposite strands.

The irradiation of nucleic acids ruptures hydrogen bonds that hold DNA strands together results in deamination and dehydroxylation of purine and pyrimidine bases, fission of sugar base linkage, liberation of the purine bases, destruction of the pyrimidine bases, oxidation of the sugar moiety, and breakage of the nucleotide chain with liberation of inorganic phosphates. In the presence of oxygen, irradiation leads to the formation of hydroperoxides of the pyrimidine bases but not of the purine bases.

In general, the purine bases appear to be much more stable to radiolysis than pyrimidine bases. This is probably owing to the greater π -delocalization energy of the purines, which provides a pathway for nondestructive energy dissipation. Furthermore, the pyrimidine bases are known to undergo free radical reactions more readily than the purine bases. The order adenine > guanine > cytosine

> uracil > thymine has been established for the relative stabilities of the bases to radiolysis. In the presence of oxygen in aqueous solution, uracil and thymine form stable hydroperoxides, whereas cytosine forms an unstable hydroperoxide that decomposes to a variety of products.

Irradiation of DNA in the solid state at liquid nitrogen temperature yields radicals in which, electron spin resonance measurements indicate, the unpaired spin is delocalized over the entire chain and does not belong to any one unit of the giant molecule. The addition of small amounts of water to this system does not alter the nature of the DNA radicals produced, but a two-to-one excess of water results in the annihilation of the electron spin resonance signal for DNA with the appearance of a strong signal due to water radicals. It has been postulated that this protective effect is attributable to energy transfer that is made possible in an excess of water by structuring of the water, thus providing a pathway for the formation of a delocalized water radical, or exciton. Electron spin resonance studies of irradiated nucleoprotein solutions indicate that the protein takes most of the radiation damage, protecting the nucleic acid moiety.

The damages caused by ionizing radiations in nucleic acid and their components are obviously detrimental to the passage of genetic information that requires specific order of intact purine and pyrimidine bases in the DNA strands. Alterations in these bases and the DNA molecules in general can lead to mutations and lethal genes. The disruption of RNA molecules interferes with protein synthesis and can result in eventual cell death.

RESPONSE OF BIOLOGICAL SYSTEMS TO IONIZING RADIATION

Identification of the Critical Target

As noted previously, absorption of ionizing radiation energy depends on the atomic weights of the atoms of the material and the density of the material. In contrast to the absorption of ultraviolet and visible radiation, the absorption of ionizing radiation is virtually independent of the nature of the molecular structure. Thus, the release of ionizing radiation energy in biological systems is essentially independent of the molecular bonds contained in the different biological molecules. This complicates the task of identifying the critical actions of this type of radiation. A good understanding of the action of ionizing radiation on living cells requires that the biologically important events should be known.

Determination of the critical sites for killing and mutagenesis by ionizing radiation has required biological

experiments designed to answer this question. Several criteria essential for a target to qualify as a critical site for radiation action include: 1) relatively large size, 2) one or only a few copies in the cell, and 3) that it should serve a critical function for the growth and survival of the cell. The first two criteria result from the statistical distribution of damaging events in the cell. From target theory, it has been shown that the physical distribution of energy released from ionizing radiation follows a Poisson statistical distribution. Therefore, the most likely targets to be damaged are those with the first two criteria. The two cellular components that best satisfy all three criteria are the genomic material (DNA) and the cytoplasmic membrane.

Evidence Supporting DNA as a Critical Target

DNA is considered as one of the plausible critical targets for radiation action because there is only one or a few copies of the genome in each cell, because it is large compared with other molecular components, and because it plays a critical role in the proliferation and survival of the cell.

The most compelling pieces of experimental evidence that DNA is a critical target for the biological action of ionizing radiation are the mutagenic effects of ionizing radiation and the existence of DNA repair-deficient mutants of bacteria and cultured mammalian cells, which display a high sensitivity to killing by ionizing radiation.

Cellular genetic information is determined by the base sequence of the genomic DNA. Any alterations in this base sequence, such as damage to the bases in DNA (see above), will result in changes to this base sequence and, thus, to potentially mutagenic events. Whether the base sequence change will result in a phenotypic change depends on exactly where the base change occurs. If it is in an essential region of the DNA for the gene coding for a protein product or some functional or structural RNA product (tRNA or rRNA), then the base change will give rise to a phenotypic mutant. Otherwise, the mutation will fall into the category of a "silent mutation," which refers to those genotypic changes that do not have any associated phenotypic changes. For either type of mutation, the DNA is the component that must undergo change for the mutagenic event to occur.

An important advance in the understanding of how radiation kills biological systems involved the discovery that certain cells were more sensitive to killing by radiation than others. This discovery was first observed with the killing of bacteria by ultraviolet radiation.

In the case of ultraviolet radiation, it was rather straightforward to establish that the biochemical damage involved in this differential sensitivity of cells was in DNA and, more specifically, that it was the result of the formation of intrastrand (or, much less frequently, interstrand) cyclobutane pyrimidine dimers. Several factors facilitated the identification of this type of damage. First, pyrimidines absorb ultraviolet light strongly at 260 nm, and the efficiency of killing by ultraviolet radiation is maximal at or near this wavelength. Second, there was available a sensitive and quantitative assay for this type of damage. Thus, it was possible to quantitatively measure this biochemical damage and establish its relation to biological killing by the ultraviolet radiation.

Several decades later (in the 1960s), the same differential sensitivity of bacteria to killing by ionizing radiation was observed, and the biochemical damage responsible for this differential sensitivity was determined to be single-strand breaks in the backbone of the DNA. DNA strand breaks can be measured by a sensitive assay, using agarose gel electrophoresis, thus affording the opportunity to quantitatively relate the production of strand breaks with cell killing. Additionally, the isolation of radiation-sensitive mutants that lacked the ability to efficiently repair strand breaks was achieved. Thus, there was good evidence that this type of damage was related to the killing action of ionizing radiation.

Evidence that the Cytoplasmic Membrane Is a Critical Target

The cytoplasmic membrane is critical for the survival of the cell. It is large, and there is only one present for each cell. Therefore, the cytoplasmic membrane has the key characteristics that make it a likely critical target for killing by ionizing radiation. Experimental evidence that the membrane plays a role in the lethal action of ionizing radiation involves the observation that oxygen increases the radiosensitivity of cells to killing by ionizing radiation. This radiosensitization by oxygen during radiation exposure is commonly called the oxygen effect and is active in the killing of bacteria, mammalian cells, and plant cells, but not viruses. Also, the biological inactivation of free DNA (either viral or transforming DNA) by ionizing radiation does not display the oxygen effect.

As a result of the different responses to the oxygen effect, it is common to refer to the killing action of ionizing radiation including a component that is oxygen-dependent and one that is oxygen-independent damage.

Each of these results in cell-killing. The oxygen-independent damage is considered to be damage that involves the DNA, and the oxygen-dependent damage is considered to be that to the cytoplasmic membrane. Typically, the efficiency of killing by ionizing radiation is two to four times greater when exposure occurs in the presence of oxygen compared with when exposure occurs in an anoxic environment. Thus, it is reasonable to predict that between 50 and 75% of the lethal action of ionizing radiation results from membrane damage. For the oxygen effect to occur, the oxygen must be present during radiation exposure.

Relative Sensitivity of Various Biological Systems to Killing by Ionizing Radiation

To design a protocol for sterilization of a solution or material by ionizing radiation, it is necessary to establish the exposure dose required to kill all living organisms present, which is the definition of the sterilization dose. There is a large amount of data that provides measures of the radiosensitivity of diverse biological systems to radiation. For pharmaceuticals, it is important to consider viruses as well as pathogenic bacteria and other pathogenic organisms when determining the exposure dose required for sterilization of a particular product. It is also necessary to consider the physical and chemical environmental factors that cause variations in radiation sensitivity when establishing sterilization doses for the material, for the reasons that have been addressed previously. In general, the most radioresistant biological systems are the viruses. Certain bacterial species (e.g., *Micrococcus radiodurans*) are as resistant as many viruses. The 37% survival dose for these radioresistant bacteria is approximately 20 kGy (2 Mrad).

Fig. 2 Biological survival curves.

Survival Curves for Microorganisms

Ultimately, the goal of ionizing radiation treatment of pharmaceuticals is to kill all living organisms, that is, to sterilize the product. To achieve this, it is important to understand and know the survival curve response of microorganisms to killing by radiation. Fig. 2 displays the various kinds of survival curves that may be observed for microorganisms. No numbers have been assigned to the axes, because only the overall kinetic response of killing by the radiation is of interest. Curves *a* and *b* show the killing action for two hypothetical organisms with the same rate of killing but with differing repair capacities. Organisms capable of repairing lethal damage will have a characteristic threshold dose below which there is complete survival from radiation exposure. As the radiation dose increases, the repair system is not able to completely repair all radiation damage, and there is an exponential decrease in the viability of the population with increasing radiation doses. Alternatively, requirement for multiple ionization events in a critical target, or ionization events in multiple targets, can give rise to a threshold dose below which there is no observed radiation killing.

Curves *c* and *d* show the killing of organisms that lack the “shoulder” portion of curves *a* and *b*. The slope of the survival curve for organism *d* is greater than for organism *c* because organism *d* is more sensitive to radiation killing than organism *c*. Two organisms may differ in both the values of their threshold doses and in their kinetics of inactivation by radiation. It is important to keep in mind the shape and rate of inactivation of unwanted organisms when designing protocols for radiation sterilization.

USE OF IONIZING RADIATION IN THE PREPARATION OF STERILE PHARMACEUTICALS FOR HUMAN USE

At this writing, there are no approved procedures for the preparation of sterilized pharmaceuticals by exposure to ionizing radiation, although several packaging materials are approved for sterilization by doses in the 5- to 25-kGy dose region. The U.S. Food and Drug Administration (FDA) is considering rules that would permit the use of ionizing radiation in the terminal sterilization of drugs for human use. The two processes under consideration are aseptic processing and terminal sterilization for the preparation of sterile pharmaceuticals. These two methods differ in the manner by which sterilization of the product is achieved. In the case of aseptic processing, the product and the container are sterilized separately, and then final packaging of the product is carried out under aseptic

conditions. When terminal sterilization is used, the finally packaged product is sterilized. The FDA favors the terminal sterilization approach because fewer failures occur when using this technique compared with the failure rate of the aseptic processing techniques. When using terminal sterilization, the step of transfer of the product into the sterilized container under aseptic conditions is avoided, thus removing the possibility for product contamination during the transfer step. It is recognized that it will not be practical to use terminal sterilization for certain pharmaceuticals, since they might be sensitive to alteration and inactivation by the sterilizing agent, whereas they can be sterilized by filtration, when in solution.

During ongoing deliberations of which techniques should be approved by the FDA for the preparation of sterilized pharmaceuticals, the two physical methods under consideration are heat and ionizing radiation. Concerns similar to those associated with the use of ionizing radiation in food processing have been raised. After extensive discussions and hearings, the FDA has approved the commercial use of ionizing radiation for processing fruits, vegetables, poultry, beef, and spices. Before this technique is approved by the FDA as a physical agent for sterilization of pharmaceuticals, similar hearings will be required. The primary issue to be considered when developing a protocol using ionizing radiation is the establishment of the minimum and maximum allowable exposure doses. A minimum dose limit is required, to ensure that the product has been exposed to a sufficiently high dose that results in sterilization of the product. A maximum dose limit is required to avoid damage to the product resulting from unnecessarily high exposure doses. Exposure dose limits in the FDA regulations for food processing include minimum and maximum acceptable dose limits, which were established with these goals in mind.

Experiments on the action of ionizing radiation on pharmaceuticals and the killing of bacteria by ionizing radiation indicate that this treatment has the potential to be used in terminal sterilization. Reports indicate that there are no products formed in irradiated samples of penicillin G, neomycin, novobiocin, and dihydrostreptomycin, which are different from those that are formed by acidic, basic, hydrolytic, and oxidative treatments of these antibiotics. At the same exposure doses, there was a 1 million-fold reduction in the number of viable bacterial spores, which are the most radiosensitive forms of endospore forming bacteria. Thus, the use of ionizing radiation may provide an alternative to heat or chemical treatment for the sterilization of pharmaceuticals. This could provide a solution to the problem of sterilization of heat-sensitive drugs. Also, avoidance of chemical sterilization removes the possibility of contamination by residues of the chemical that was used

for sterilization. It has been reported that irradiation of the antibiotic cefotaxime formed radiation products from impurities present in the cefotaxime sample. One must be aware of the role of solvents and chemicals other than the drug itself when considering radiolytic changes of a drug during sterilization.

CONCLUSIONS

The purpose of this article is to provide the pharmaceutical industry with an overview of the physical, chemical, and biological actions of ionizing radiation on molecules of interest to the industry, as well as to provide a current perspective on the prospects of the practical use of ionizing radiation as a physical agent in the sterilization of drugs for human use. Advantages of using employing ionizing radiation for pharmaceutical sterilization include:

- effectiveness on all microorganisms;
- no rise in temperature during treatment;
- consistent and reproducible protocols; and
- readily controlled and validated methods.

Although there is currently no approval by the FDA for ionizing radiation sterilization, there are active hearings being held by the agency on this matter. Considering the desire by the FDA to encourage the terminal sterilization method for sterilization of pharmaceuticals and the fact the ionizing radiation has distinct advantages over other treatment methods for use in terminal sterilization as presented above, it is expected that there will be approval of the use of this physical agent in sterilization of drugs for human use after regulatory hearings have provided sufficient information to allow identification of the appropriate conditions under which this agent can be used. Recent developments in the

application of ionizing radiation for sterilization are reported on Web sites <http://www.iaea.org> and <http://www.fda.gov>.

INTRODUCTION

Disintegrating agents are substances routinely included in tablet formulations and in some hard shell capsule formulations to promote moisture penetration and dispersion of the matrix of the dosage form in dissolution fluids. An oral solid dosage form should ideally disperse into the primary particles from which it was prepared. Although various compounds have been proposed and evaluated as disintegrants, relatively few are in common usage today. Traditionally, starch has been the disintegrant of choice in tablet formulations, and it is still widely used. However, starch is far from ideal. For instance, starch generally has to be present at levels greater than 5% to adversely affect compactibility, especially in direct compression. Moreover, intragranular starch in wet granulations is not as effective as dry starch. In more recent years, several newer disintegrants have been developed. Often called "super disintegrants," these newer substances can be used at lower levels than starch. Because they can be a smaller part of the overall formulation than starch, any possible adverse effect on fluidity or compactibility would be minimized. These newer disintegrants may be organized into three classes based on their chemical structure (Table 1).

GENERAL CHEMISTRY AND SURFACE MORPHOLOGY

Sodium Starch Glycolate

Sodium starch glycolate is a super disintegrant made from cross-linking sodium carboxymethylstarch (1). Cross-linking involves a chemical reaction with phosphorus oxytrichloride or sodium trimetaphosphate, or a physical

manipulation. Carboxymethylation is performed by reacting starch with sodium chloroacetate in an alkaline medium and neutralizing with a citric or acetic acid, a process known as a Williamson ether synthesis. This synthesis yields carboxymethylation of about 25% of the glucose units. The by-products, which include sodium chloride, sodium glycolate, and sodium citrate or acetate, are partially washed out. The particle sizes of the disintegrants are increased by the substitution and cross-linking processes (3).

Sodium starch glycolates are generally spherical, a characteristic that accounts for their good flowability (4). Figure 1 shows the scanning electron photomicrographs of some of the commercially available sodium starch glycolates.

Croscarmellose Sodium

Croscarmellose sodium is derived from internally cross-linking a cellulose ether, sodium carboxymethylcellulose, which is a water soluble polymer. It is composed of repeating units of cellobiose units, with each unit consisting of two anhydroglucose units linked by 1,4- β -glucoside. Each unit also has three hydroxyl groups. The degree of substitution refers to the average number of hydroxyl groups substituted by carboxymethyl groups. Croscarmellose sodium is made from crude cellulose, which is steeped in sodium hydroxide solution (1). The cellulose is subsequently reacted with sodium monochloroacetate to form carboxymethylcellulose sodium. After completion of the substitution, the excess sodium monochloroacetate slowly hydrolyzes to glycolic acid. The glycolic acid converts a few of the sodium carboxymethyl groups to the free acid, catalyzes the cross-linkage to form croscarmellose sodium, and forms sodium chloride and sodium glycolate as the by-products.

Table 1 Classification of “super disintegrants” (partial listing)

Structural type (NF name)	Description	Trade name (manufacturer)
1. Modified starches (Sodium starch glycolate, NF)	Sodium carboxymethyl starch; the carboxymethyl groups induces hydrophilicity and cross-linking reduces solubility.	Explotab [®] (Edward Mendell Co.) Primojel [®] (Generichem Corp.) Tablo [®] (Blanver, Brazil)
2. Modified cellulose (Croscarmellose, NF)	Sodium carboxymethyl cellulose which has been cross-linked to render the material insoluble.	AcDiSol [®] (FMC Corp.) Nymcel ZSX [®] (Nyma, Netherlands) Primellose [®] (Avebe, Netherlands) Solutab [®] (Blanver, Brazil)
3. Cross-linked poly-vinylpyrrolidone (Crospovidone, NF)	Cross-linked polyvinylpyrrolidone; the high molecular weight and cross-linking render the material insoluble in water.	Crospovidone M [®] (BASF Corp.) Kollidon CL [®] (BASF Corp.) Polyplasdone XL (ISP Corp.)

Most of the by-products can be removed to achieve 99.5% purity by extraction with alcohol. Croscarmellose sodium may be milled to break the polymer fibers into shorter lengths and hence improve its flow properties.

Unlike sodium starch glycolate, crude croscarmellose sodium particles do not flow very well because of their twisted fibrous morphology and varying lengths. Therefore, they are cryogenically milled to improve flowability. The scanning electron photomicrographs show that the croscarmellose sodium particles are fibers with fairly sharp ends, probably because of the milling process (Fig. 2).

Crospovidone

Crospovidone is a cross-linked homopolymer of *N*-vinyl-2-pyrrolidone. The reactants, acetylene and formaldehyde, are used to form butynediol. The hydrogenation and subsequent cyclodehydrogenation of butynediol form butyrolactone. The reaction of butyrolactone with ammonia produces pyrrolidone that is then vinylated with acetylene under pressure. The linear polymerization of the vinylpyrrolidone yields polyvinylpyrrolidone, a soluble binder, while the popcorn (branched) polymerization yields crospovidone, an insoluble super disintegrant. The by-products of popcorn polymerization include vinylpyrrolidone and polyvinylpyrrolidone. Crospovidone contains less than 1.5% of the soluble material, which has been determined to be polyvinylpyrrolidone by infrared spectroscopy.

Crospovidone particles have a very different appearance from those of the other two classes of super disintegrants. Crospovidone particles seem to consist of aggregates of smaller particles that are fused together. This aggregation gives crospovidone a spongy, highly porous

appearance (Fig. 3). Scanning electron photomicrographs show that the reduction of particle size of crospovidone increases the surface area per unit weight, but decreases the intraparticulate porosity and the spongy appearance (4).

DISINTEGRANT ACTION

Although disintegrants are important components in solid dosage forms, their mechanism of action has not been clearly elucidated. The mechanisms proposed in the past include water wicking, swelling, deformation recovery, repulsion, and heat of wetting. It seems likely that no single mechanism can explain the complex behavior of the disintegrants. However, each of these proposed mechanism provides some understanding of different aspects of disintegrant action.

Water Wicking

The ability of a disintegrant to draw water into the porous network of a tablet is essential for effective disintegration. For crospovidone, water wicking has been thought to be the main mechanism of disintegration. Kornblum and Stoopak (5) observed that crospovidone swells very little, yet takes water into its network quite rapidly. Even the extensively swelling sodium starch glycolate showed improved disintegration when the molecular structure was altered to improve water uptake, as observed by Rudnic et al. (6). Unlike swelling, which is mainly a measure of volume expansion with accompanying force generation, water wicking is not necessarily accompanied by a volume increase.

Fig. 1 Scanning electron photomicrograph of sodium starch glycolates: (A) Explotab[®], (B) Primojel[®], and (C) Tablo[®] (600× magnification).

The ability of a system to draw water can be summarized by Washburn's equation (7):

$$L^2 = \left(\frac{\gamma \cos \theta}{2\eta} \right) rt \quad (1)$$

The Washburn equation is too simplistic to apply to a dynamic tablet-disintegration process, but it does show that any change in the surface tension (γ), pore size (r), solid-liquid contact angle (θ), or liquid viscosity (η) could change the water wicking efficiency (L = length of water penetration in the capillary; t = time). For example, when Rudnic et al. (8) evaluated the disintegration efficiency of different particle sizes of crospovidone, those with the largest particle size range (50–300 μm) yielded the shortest disintegration time. Large particle size probably yielded greater pore size and altered the shape of the pore. Indeed, longer fiber length due to greater particle size could improve the efficiency of capillary uptake of water into the dosage form matrix.

Super disintegrants draw water into the matrix system at a faster rate and to a greater extent when compared to traditional starch (9). Van Kamp et al. (10), utilizing a water uptake measurement device, were able to show that tablets that demonstrate greater uptake volume and rate, such as those containing sodium starch glycolate, disintegrated more rapidly. Although the hydrophobic lubricant, magnesium stearate, seemed to negatively affect the wicking process, those containing sodium starch glycolate were less affected by the detrimental effect of mixing with the hydrophobic lubricant. Lerk et al. (11) also observed a decreased rate of wetting when disintegrants were mixed with magnesium stearate for various mixing times. The decrease in the rate of wetting was proportional to the time of mixing. Most likely, this observation reflected a greater delamination of magnesium stearate at longer mixing times.

Swelling

Although water penetration is a necessary first step for disintegration, swelling is probably the most widely accepted mechanism of action for tablet disintegrants. Indeed, most disintegrants do swell to some extent, but the variability of this property between disintegrants reduces its plausibility as a sole mechanism.

The earliest attempt to measure swelling was to measure the sedimentation volume of slurries. Nogami et al. (12) developed a reliable test to measure both swelling and water uptake. Gissinger and Stamm (13) modified this apparatus and found a positive correlation between the rate of swelling and disintegrant action for some disintegrants. List and Muazzam (14) later adapted this apparatus to measure both rate of swelling and swelling force through the application of force and displacement transducers. They found that disintegrants that generate large swelling forces are generally more effective.

Fig. 2 Scanning electron photomicrograph of croscarmelloses: (A) AcDiSol[®], (B) Nymcel ZSX[®], (C) Primellose[®], and (D) Solutab[®] (100× magnification).

For swelling to be effective as a mechanism of disintegration, there must be a superstructure against which the disintegrant swells. Swelling of the disintegrant against the matrix leads to the development of a swelling force. A large internal porosity in the dosage form in which much of the swelling can be accommodated reduces the effectiveness of the disintegrant. At the same time, a matrix that yields readily through plastic deformation may partly accommodate any disintegrant swelling if swelling does not occur at a sufficient rapidity.

The swelling of some disintegrants is dependent on the pH of the media. Shangraw et al. (3) reported that sedimentation volumes of anionic cross-linked starches and celluloses are altered in acidic media. Polyplasdone XL[®] and Starch 1500[®] were unchanged. In a separate

study, Chen et al. (15) showed that acetaminophen tablets containing Primojel[®] and AcDiSol[®] had longer disintegration and dissolution times in acidic medium compared to neutral medium. Those containing Polyplasdone XL[®] showed no such differences. Mitrevej and Hollenbeck (16) verified the remarkable swelling capacity of some “super disintegrants” by exposing individual particles deposited on slides to high humidities and observing their degree of swelling microscopically.

On the other hand, when Caramella et al. (17–19) evaluated different disintegrants for their ability to swell, no correlation could be observed between the maximum disintegrating force and percent of particle swelling. Because they did observe a correlation between the rate of disintegrating force development and the disintegration

Fig. 3 Scanning electron photomicrograph of crospovidones: (A) Crospovidone M[®], (B) Kollidon CL[®], (C) Polyplasdone XL[®], and (D) Polyplasdone XL-10[®] (150× magnification).

time, therefore, the authors suggested that the rate of development of a disintegrating force is all-important. Swelling capable of rapid force development may be preferred since a slowly developing force could hypothetically allow tablets to relieve the stress generated without bond disruption.

Deformation Recovery

The deformation recovery theory implies that the shapes of the disintegrant particles are distorted during compression, and that the particles return to their precompression shape upon wetting, thereby causing the tablet to break apart. Hess (20), with the aid of photomicrographs, showed that

deformed starch particles returned to their original shape when exposed to moisture.

Fassihi (21) concluded that at higher compression forces, disintegration may become dependent on mechanical activation of the tablet, resulting from the stored energy imparted by the compression process. He examined the disintegration times of tablets made of Emdex[®] powder, magnesium stearate, and 5% disintegrant. Regardless of the disintegrant used (sodium starch glycolate, microcrystalline cellulose, croscarmellose sodium, or starch), the disintegration time increased with increasing compression force, then decreased again when the compression force was above 120 MN/m⁻².

Research on deformation and its recovery in situ as a disintegration mechanism is incomplete. However, such a

mechanism may be an important aspect of the mechanism of action of disintegrants such as croscopovidone and starch that appear to exhibit little or no swelling. The efficacy of such disintegrants likely would be dependent on the relative yield strength of the disintegrant and that of the matrix in which it is compressed, since disintegration efficiency would surely depend on how much deformation is sustained by the disintegrant particles. Also, time-dependent stress relaxation could possibly be a factor in the aging of such tablets in that any deformation induced into the disintegrant, that cannot be sustained by intraparticulate bonding, gradually may recover as the matrix relaxes.

Repulsion Theory

Ringard and Guyot-Hermann (22) have proposed a particle–particle repulsion theory to explain the observation that particles that do not swell extensively, such as starch, could still disintegrate tablets. In this theory, water penetrates into the tablet through hydrophilic pores and a continuous starch network that can convey water from one particle to the next, imparting a significant hydrostatic pressure. The water then penetrates between starch grains because of its affinity for starch surfaces, thereby breaking hydrogen bonds and other forces holding the tablet together. Presently, this theory is not supported by adequate data.

Heat of Wetting

Matsumara (23) noticed that starch particles exhibit slight exothermic properties when wetted, which was thought to cause localized stress resulting from expansion of air retained in the tablet matrix. Unfortunately, this explanation, if valid, would be limited to only a few substances such as aluminum silicate and kaolinite. List and Muazzam (24) found that exothermic wetting reactions were not exhibited with all disintegrants and that even when a significant heat of wetting was generated, disintegration time did not always decrease. Caramella et al. (25) found that an increase in temperature, which should cause air expansion, did not enhance maximum force generation in several formulations. Therefore, they concluded that expansion of air in pores from heat of wetting could not be supported by the data. More recently, Luangtana-anan et al. have examined the heat of wetting of powders and tablets of magnesium carbonate and Emcompress® (26).

Magnesium carbonate tablets with significantly higher heat of wetting disintegrated more readily than the Emcompress® tablets. Indeed, it would be interesting to

develop a model for the mechanism of tablet disintegration using a thermodynamic approach; however, heat of wetting alone probably is inadequate to explain disintegration.

Generation of a Disintegrating Force or Pressure as a Unifying Principle

The rate of generation of a disintegrating force may be a unifying factor in the mechanisms of disintegration (19). Many proposed mechanisms may be visualized as giving rise to a force. Brzezczko (27) developed techniques to simultaneously measure the rate of liquid uptake into a tablet and the rate of generation of both axial and radial swelling forces. As indicated in Figs. 4, 5, and 6, tablet compaction contributes more to the axial pressure than to the radial pressure when super disintegrants representing the three main super disintegrant classes were studied in model tablet formulations. In all three cases, the maximum axial pressure in an anhydrous lactose matrix was well below that observed with a dicalcium phosphate dihydrate matrix when the disintegrants are compared at the same concentration. The differences in disintegrant performance in soluble and insoluble matrices could be rationalized in terms of pressure development and liquid uptake. Fig. 7 compares the maximum axial disintegrating pressure and disintegration times of the tablets containing 2% of the disintegrants in a matrix composed of dicalcium phosphate or lactose (27). As can be seen, a higher disintegration pressure favors rapid disintegration of the dicalcium phosphate-based tablets, but a slower disintegration of lactose-based tablets. Higher initial axial disintegrating pressure rates also yield shorter disintegration times for the dicalcium phosphate-based tablets, but no such correlation is seen with the lactose-based tablets, whose disintegrating pressure rates are much lower than those of the dicalcium phosphate-based tablets (see Fig. 8). Maximum water uptake and water uptake rate seem to be poor predictors of disintegration time, as seen in Figs. 9 and 10. However, lactose-based tablets show a trend toward slower disintegration with faster liquid uptake. It was suggested that faster liquid uptake leads to a faster dissolution of lactose and increased porosity to accommodate swelling and/or structural recovery.

Peppas (28) attribute the difference in disintegration rate between soluble and insoluble matrices to two proposed phenomena — an interface-controlled mechanism and a diffusion-controlled mechanism — as represented in the following equation:

$$F/F_{\infty} = 1 - \exp(-kt^n) \quad (2)$$

Fig. 4 The effect of compression pressure on the axial and radial disintegrating pressures of compacts made with lactose or DiTab[®], and AcDiSol[®] (5%). (From Ref. 27.)

Here, F is the disintegration force at time t , F_{∞} is the maximum force developed, k is an expansion rate constant, and n signifies which of the two mechanisms controls the disintegration. The interface controlled phenomenon involves tablet particles breaking apart from the interface of the tablet and the diffusion-controlled phenomenon

involves particles diffusing away. Although it is thought that both happen simultaneously, the degree to which disintegration depends on each system can differ. For example, those tablet matrices with a relatively small n of about 0.6 are thought to be dominated by the diffusional mechanism; whereas, those with an n of greater than

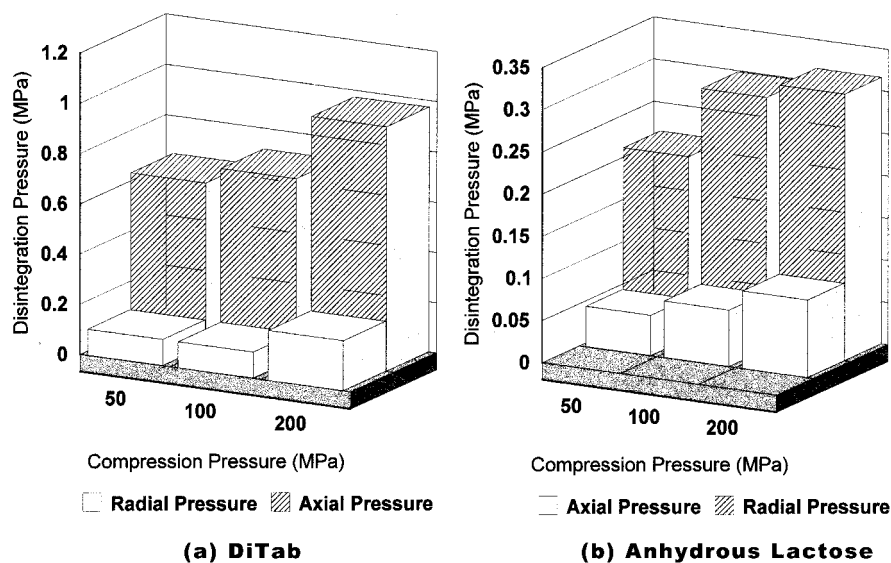

Fig. 5 The effect of compression pressure on the axial and radial disintegrating pressures of compacts made with lactose or DiTab, and Primojel[®] (5%). (From Ref. 27.)

Fig. 6 The effect of compression pressure on the axial and radial disintegrating pressures of compacts made with lactose or DiTab, and Polyplasdone XL[®] (5%). (From Ref. 27.)

0.9 are thought to be interfacial mechanism dominant. The value of n would certainly differ based on the solubility of the matrices.

Since super disintegrants are highly hydrophilic yet insoluble in water, they would be expected to be more effective in breaking the tablet apart interfacially than controlling the diffusion per se. Indeed, Caramella et al. observed that disintegration occurred readily for tablets containing insoluble calcium phosphate; whereas, tablets containing highly soluble β -lactose disintegrated slowly. Such phenomena were explained by a lower value of n for the system containing β -lactose. In other words, the super

disintegrant's interface-controlled mechanism could not overcome the diffusion-controlled mechanism of the β -lactose (29).

FACTORS AFFECTING DISINTEGRANT ACTIVITY

Particle Size

Both the rate and force of disintegrant action may be dependent upon the particle size of the disintegrant. Smallenbroek et al. (30) found that starch grains having

Fig. 7 Maximum axial disintegrating pressure versus disintegration time of dicalcium phosphate and lactose tablets containing 2% super disintegrants. \circ = Dicalcium phosphate: $r^2 = 0.92$, $p < 0.05$, significant correlation. Δ = Lactose: $r^2 = 0.81$, $p < 0.05$, significant correlation. (From Ref. 27.)

Fig. 8 Initial axial disintegrating pressure rate versus disintegration time of dicalcium phosphate and lactose tablets containing 2% super disintegrants. \circ = Dicalcium phosphate: $r^2 = 0.95$, $p < 0.05$, significant correlation. Δ = Lactose: $r^2 = 0.10$, $p < 0.05$, no significant correlation. (From Ref. 27.)

Fig. 9 Maximum water uptake versus disintegration time of dicalcium phosphate and lactose tablets containing 2% super disintegrants. ○ = Dicalcium phosphate: no significant correlation. △ = Lactose: no significant correlation. (From Ref. 27.)

relatively large particle sizes were more efficient than the smaller particle size grades. This is probably because the continuous hydrophilic network of disintegrants is more efficiently accomplished by the bigger particles. Also, Rudnic et al. (8) found that coarser grades of crospovidone (50–100 μm , Grade B; 50–300 μm , Grade C) were more efficient than the finer particles (0–15 μm , Grade A). The differences in disintegration efficiency between Grade B and Grade C were not clear, however. When List and Muazzam (24) evaluated two different grades of crospovidone particles (100–200 μm and >315 μm), the efficiencies between the two grades were very similar (see Table 2). Results for the other disintegrants, Amberlite IRP88[®] and potato starch, support that coarser particle sizes allow more efficient disintegration than finer particles. For disintegrants that swell extensively, such

Fig. 10 Initial water uptake rate versus disintegration time of dicalcium phosphate and lactose tablets containing 2% super disintegrants. ○ = Dicalcium phosphate: no significant correlation. △ = Lactose: $r^2 = 0.47$, $p < 0.05$, no significant correlation. (From Ref. 27.)

efficiency can be explained by the observed force development. Indeed, larger particles of sodium starch glycolate swelled more rapidly and to a greater extent than did the smaller particles (6).

Molecular Structure

Disintegrants can vary in molecular structure based on how they are manufactured or processed. Corn starch, for example, contains different ratios of two sugar fractions, amylose and amylopectin. Schwartz and Zelinske (31) concluded that the linear polymer, amylose, was responsible for the disintegrant properties associated with starch, whereas the branched polymer, amylopectin, was responsible for the gummy property.

Table 2 Effect of particle size and compression pressure on swelling pressure and disintegration time

Disintegrant	Compression pressure (bar)	Particle size (μm)	Swelling pressure (bar)	Disintegration time (s)
Amberlite IRP88 [®]	625	<50	0.660	84
	1560	<50	1.121	30
Amberlite IRP88 [®]	625	100–200	1.083	52
	1560	100–200	2.262	22
Potato starch	625	<50	0.165	254
	1560	<50	0.310	164
Potato starch	625	80–100	0.234	160
	1560	80–100	0.445	77
Polyplasdone XL [®]	625	100–200	0.898	31
	1560	100–200	1.772	14
Polyplasdone XL [®]	625	>315	0.760	42
	1560	>315	1.480	17

Tablet composition: 2.5% disintegrant, 1% magnesium stearate, and Emcompress[®]. (From Ref. 24.)

Varying the amylose to amylopectin ratio did not affect the porosities of the resulting tablets. Rudnic et al. (6) evaluated the effect of cross-linking and carboxymethyl substitution in sodium starch glycolate and concluded that the swelling of the disintegrant was largely inversely proportional to the degree of cross-linkage. Swelling also was inversely proportional to the level of substitution, but to a lesser degree. Shah et al. (32) found that carboxymethyl cellulose having high molecular weight and low levels of carboxymethylation was best for tablet disintegration.

Effect of Compression Force

Compression force affects disintegration time in different ways. First, it governs the penetration of dissolution fluids into the matrix by controlling the porosity of the compact. Low compression force can lead to relatively high tablet porosity and can allow rapid penetration of water. However, it has often been observed that tablets containing starch exhibit disintegration times that tend to pass through minimum as compression force increases (21). At low compression forces, any possible swelling or deformation recovery that may take place may be more or less accommodated by the porosity, whereas at intermediate compression forces, a maximal disintegrating effect may develop. At high compression forces, fluid penetration may be impeded by a further reduction of porosity while particle deformation of the disintegrants becomes more important. In general, List and Muazzam (14) found increased swelling pressures at higher compression forces when various amberlite resins, starches, and crospovidones were employed at the 2.5% level in dicalcium phosphate matrix tablets (see Table 2). Similar findings were reported by and Fassihi (21) and Brzezko (27).

In two different studies Khan and Rhodes (33, 34) observed that tablets containing sodium starch glycolate disintegrate relatively slowly at low compression force, quickly at intermediate compression force, and slowly again at high compression force. However, the effects of compression force on the disintegration time of other types of disintegrants, such as cation exchange resin, calcium sodium alginate, and various forms of starches, varied widely. Perhaps the effect of compression force on the disintegration time depends on the nature of the disintegrants, such as their mechanism of disintegration and deformation characteristics.

Munoz et al. (35) found that the effect of compression pressure on disintegration time varied depending on the concentration used of the super disintegrant, Explotab®. Fig. 11 shows that shortest disintegration time could be

Fig. 11 Surface response of disintegration time as functions of compression pressure and percent disintegrant. (From Ref. 11.)

achieved at around 7% disintegrant concentration. At this concentration, compression force has little effect on disintegration time. The disintegration time was more affected by compression force at low disintegrant concentration, showing fastest disintegration time at intermediate compression force. This type of biphasic effect of compression force on disintegration time also was observed for AcDiSol® (36), and the surface response curve is very similar to that of Explotab®. When disintegration times were studied at 5 and 10% disintegrant, 5% AcDiSol® yielded the lowest porosity, lowest yield pressure in Heckel analysis, and shortest disintegration time. At a 10% disintegrant level, the tablets showed a slight postcompression expansion, which could explain a slightly increased disintegration time compared to the 5% disintegrant level.

The effect of compression force on disintegration efficiency seems, therefore, largely dependent on the mechanism of the disintegrant action. The effectiveness of swelling or structure recovery may well be dependent on attaining a compression force that achieves a critical porosity in the matrix. On the other hand, the capillary uptake of liquid, which is a necessary precursor to these mechanisms could be compromised if the tablet matrix is compressed to too low a porosity.

Matrix Solubility

The disintegrant mechanism seems to depend not only on the disintegrant itself but on the matrix as well. Disintegrants work most effectively in insoluble matrices

(27). Insoluble matrices, such as those containing calcium phosphate do not disintegrate adequately without disintegrants. On the other hand, tablets and capsules that primarily consist of water soluble fillers or drugs tend to dissolve rather than to disintegrate, even when disintegrating agents are present. It has been suggested that during the dissolving process, the water acts as a plasticizer (37), which can potentially reduce the development of disintegrating force. In addition, soluble materials that tend to swell can form viscous plugs, which may impede further penetration of moisture into the matrix. However, the addition of disintegrants almost predictably shortens disintegration time, despite the solubility of the matrix.

Method of Incorporation in Granulation

The method of incorporation of disintegrants in granulation has been controversial. Should the disintegrant be all extragranular, all intragranular, or divided between these two locations? Shotton and Leonard (38) reported that maize starch, sodium calcium alginate, alginic acid, and other disintegrants gave more rapid disintegration when incorporated extragranularly than when incorporated intragranularly in a sulfadiazine granulation. They also reported that the latter method gave a finer dispersion and concluded that the best compromise was to use both intra- and extragranular disintegrant.

Van Kamp et al. (39) evaluated the method of incorporation of Primojel[®], AcDiSol[®], and Polyplasdone XL[®] in prednisone tablets formed from lactose granules. Whether the incorporation of the super disintegrant was intragranular, extragranular, or evenly distributed in both sites, they found little or no difference in disintegration time, crushing strength, or dissolution of prednisone. Interestingly, their results with potato starch showed differences that did not agree with the earlier work of

Shotton and Leonard (38) in that intragranular starch was more effective than extragranular starch (see Table 3). Gordon et al. (40) reported that dissolution of naproxen, a poorly soluble drug at gastric pH levels, was faster when AcDiSol[®] was incorporated intragranularly, compared to when it was incorporated extragranularly or evenly distributed between the intra- and extragranular portions. Even more recently, a study reported by Khattab et al. (41) showed that the combined incorporation of intra- and extragranular disintegrating agents (sodium starch glycolate, croscarmellose sodium, or crospovidone) in a paracetamol granulation resulted in faster disintegration and dissolution than either extragranular or intragranular incorporation alone.

More studies are necessary to elucidate the effect of other factors, such as the type of binder, the type of filler, and the solubility of the matrix, which may significantly affect the effectiveness of disintegrants in different modes of incorporation. For example, Becker et al. (42) found that extragranular crospovidone was more effective in an acetaminophen tablet when the binder was maltodextrin (Licab DSH[®]), pregelatinized maize starch (Lycab PGS[®]), or low substituted hydroxypropylcellulose (L-HPC) than when polyvinylpyrrolidone or hydroxypropylmethylcellulose was the binder. In addition, the difference seen in the effectiveness of starch in different modes of incorporation between the Shotton and Leonard (38) study and the Van Kamp et al. (39) study may be related to the absence or presence of lactose, a soluble filler. Unlike the Shotton and Leonard study, Van Kamp et al. used lactose as a soluble filler, which might have reduced the relative effectiveness extragranular starch, making the intragranular incorporation more favorable.

The observations summarized in Table 4 make any attempt to generalize that one method of incorporation of disintegrant in granulation is better than another difficult.

Table 3 Effect of method of disintegrant addition in granules on the tablet properties

Disintegrant addition method	Crushing strength (kgf)			Disintegration time (s)		
	Intra	Equal	Extra	Intra	Equal	Extra
Control		6.5			664	
4% Primojel [®]	5.3	5.0	5.8	38	41	49
4% Ac-Di-Sol [®]	3.8	4.8	5.7	110	126	148
4% Nymcel zsd 16 [®]	4.0	4.3	6.5	499	540	488
4% Polyplasdone XL [®]	5.8	6.0	6.1	31	40	43
20% Potato Starch	3.3	3.4	2.1	69	80	110

(From Ref. 39.)

Table 4 Comparison of different modes of incorporation of disintegrants in granules on disintegration efficiency of tablets, as reported by different investigators

Investigators	Drug (D), Binder (B), Filler	Disintegrants evaluated	Order of disintegration efficiency	Additional comments
Shotton et al.	Sulfadiazine (D) Povidone (B) No filler	Maize starch	Extra > Intra	Extragranular incorporation yielded fastest disintegration, but intragranular incorporation yielded finer particles. Equal distribution of disintegrants is recommended.
		Na calcium alginate		
		Alginic acid		
		Microcrystalline cellulose Colloidal aluminum silicate		
Van Kamp et al.	Prednisone (D) Gelatin (B) Lactose (F)	Potato starch	Intra > Extra	The difference between the modes of incorporation for super disintegrants is not great.
		Primojel® Polyp lasdone XL® Nymcel® Croscarmellose Na	Intra > Equal > Extra Intra > Equal > Extra Extra > Intra > Equal Equal > Extra > Intra	
Khattab et al.	Paracetamol (D) Polyvinylpyrrolidone (B) No filler	Na starch glycolate Crospovidone	Equal > Intra or Extra Equal > Intra > Extra	Overall, the equal distribution of disintegrants yielded the fastest disintegration and dissolution.

(From Refs. 38, 38, and 41.)

Table 5 Rework efficiency (%RE) of super disintegrants

Disintegrant (2%)	Relative F_s (35% porosity) ^a	Relative F_s (40% porosity) ^a	% RE ^b
Control	0.842	0.848	45
Polyplasdone XL [®]	0.941	0.926	64
Explotab [®]	0.737	0.863	86
AcDiSol [®]	1.045	0.951	45

$$^a\text{Re} \cdot F_s = \frac{\text{Maximum swelling force (1st compression)}}{\text{Maximum swelling force (2nd compression)}}$$

$$^b\%RE = \frac{\text{AUC (1st compression)}}{\text{AUC (2nd compression)}}$$

AUCs are the area under curve from the disintegration time versus compression pressure graphs.

(From Ref. 44.)

However, when all of the data are taken together, it would appear that the combined addition of disintegrants both extragranularly and intragranularly would provide the best opportunity for optimal disintegrant activity.

Effect of Reworking

The effect of recompressing a wet massed microcrystalline cellulose matrix containing super disintegrants on swelling force kinetics also has been considered (43). When the disintegrants were placed extragranularly, only Explotab[®] among those considered retained good efficiency after reworking. When placed intragranularly, all disintegrants had reworking efficiencies equivalent to that of the nondisintegrant control. Adding 2% disintegrant extragranularly prior to the second compression restored disintegrant behavior for Polyplasdone XL[®], but only partial restoration was seen for AcDiSol[®]. In further work (44), reworked tablets containing 2% disintegrant extragranularly were studied. The data in Table 5 illustrate that maximal swelling forces were reduced in all cases, but there was no correlation with tablet disintegration time.

Incorporation in Hard Gelatin Capsules

The utility and performance of super disintegrants in direct-fill powder formulations for hard shell capsules filled on tamping machines are roughly analogous to those of direct compression tablet formulation. In a study where capsules were filled under controlled tamping force conditions using an instrumented Zanasi LZ 64 dosator machine, a dicalcium phosphate based formulation containing hydrochlorothiazide and different super disintegrants were tested for dissolution times (45). The croscarmelloses were found to be more effective than sodium starch glycolate in promoting hydrochlorothiazide dissolution, whereas

crospovidone was the poorest in this regard. In a follow-up multifactorial study, all main factors, including disintegrant type, compression force, level of lubricant, and filler type, were found to have significant effects on dissolution (Figs. 12 and 13) (46). In most cases at lower disintegrant concentration, increasing the tamping force improved the dissolution of hydrochlorothiazide, most likely due to reduced porosity. When the filler was changed from lactose to dicalcium phosphate, the magnitude and the order of effectiveness of the disintegrants changed.

Like the experience with tablets, the effect of disintegrants in already rapidly soluble capsule matrices is lower than that in water insoluble matrices. Perhaps doubling the concentration normally required for tablets is needed to effect efficient disintegration and significantly affect dissolution. This need for higher disintegrant concentration probably reflects the greater pore structure of capsule plugs compared to compressed tablets. At equivalent concentrations in model lactose or dicalcium phosphate-based systems, sodium starch glycolate and croscarmellose sodium were more effective than crospovidone in promoting dissolution of hydrochlorothiazide from capsules manufactured with the same tamping force (47). For either filler, disintegration times and swelling correlated well with dissolution.

NEW DISINTEGRANTS

Gellan gum and Xanthan SM[®] appear to have performance characteristics similar to those of super disintegrants. Gellan gum is an anionic polysaccharide of linear tetrasaccharides, and is derived from *Pseudomonas elodea* (48). When 4% gellan gum was incorporated in an ibuprofen tablets, its disintegration time was 4 min, which

Fig. 12 The averaged effect of disintegrant, compression force, and lubricant on the release of hydrochlorothiazide from anhydrous lactose based capsules. Control = 0% disintegrant. (From Ref. 47.)

was much superior than that obtained using dried starch or Avicel PH 102® (>15 min), and comparable to those of Explotab®, AcDiSol®, and Kollidon CL® (4–7 min).

Xanthan SM® is a new USP xanthan derivative with higher hydrophilicity and lower gelling tendency (49). In aspirin tablets with 3% Xanthan SM® disintegration time was about 10 min. Increasing the concentration of disintegrant beyond 3% did not improve the disintegration time, whereas the most effective concentration of AcDiSol® was 5%, yielding a disintegration time of less than 5 min. Xanthan SM®, like AcDiSol®, has low solubility in water, but is reported to swell more extensively in water.

Fig. 13 The averaged effect of disintegrant, compression force, and diluent on the release of hydrochlorothiazide from dicalcium phosphate based capsules. Control = 0% disintegrant. (From Ref. 47.)

SUMMARY

In summary, super disintegrants are excipients used to promote rapid breakdown of oral solid dosage forms to aid dissolution in vivo. Commonly used super disintegrants include sodium starch glycolate, croscarmellose sodium, and crospovidone. Super disintegrants differ from traditional starch in that they are effective at much lower concentrations. This lower concentration provides formulation scientists greater flexibility, particularly in designing direct compression tablets. However, the effectiveness of both starch and super disintegrants depends heavily upon

the composition of the tablet matrix, compression pressure, and in the case of granulation, the method of incorporation.

Because of the complexities involved, the mechanism of action of super disintegrants is not well understood. Some of the proposed mechanisms include water wicking, swelling, deformation recovery, particle repulsion, and heat of wetting. Water uptake is a necessary precursor to all other mechanisms. Not all mechanisms are well supported by research. Disintegrants appear to function by multiple mechanisms, but a predominant mechanism seems to be characteristic of each disintegrant type. Regardless of their validity, all proposed mechanisms at least have the potential to generate a disintegrating force within the matrix and this appears to be a unifying concept.

ACKNOWLEDGMENT

The authors wish to express sincere appreciation and gratitude to Ms. Lynn DiMemmo, FMC Co., Princeton, N.J., for the SEM's of the super disintegrants.

SURFACTANTS IN PHARMACEUTICAL PRODUCTS AND SYSTEMS

Owen I. Corrigan
Anne Marie Healy

University of Dublin, Trinity College, Dublin, Ireland

INTRODUCTION

Surface-active agents (surfactants) are substances which, at low concentrations, adsorb onto the surfaces or interfaces of a system and alter the surface or interfacial free energy and the surface or interfacial tension. Surface-active agents have a characteristic structure, possessing both polar (hydrophilic) and nonpolar (hydrophobic) regions in the same molecule. Thus surfactants are said to be amphipathic in nature. The wide range of uses for surfactants in pharmaceutical products and systems is the subject of this article.

PHYSICOCHEMICAL BACKGROUND

Surface and Interfacial Tension; Surface and Interfacial Free Energy

Atoms and molecules at surfaces and interfaces possess energies significantly different from those of the same species in the bulk phase. The term “surface” is usually reserved for the region between a condensed phase (liquid or solid) and a gas phase or vacuum, while the term “interface” is normally applied to the region between two condensed phases.

In the case of a liquid–gas interface, molecules of the liquid in the boundary can only develop attractive cohesive forces with molecules situated below and adjacent to them. They can develop attractive adhesive forces with molecules of the gaseous phase. However at the gas–liquid interface, these adhesive forces are quite small. The net effect is that molecules at the surface of the liquid have potential energies greater than those of similar molecules in the interior of the liquid and experience an inward force toward the bulk of liquid. This force pulls the molecules of the interface together and the surface contracts.

Thus, the surface of a liquid behaves as if it were in a state of tension—the surface tension (γ)—due to the contracting force acting in all directions in the plane of the surface.

In order to extend the surface of a liquid it is necessary to bring molecules from the interior to the surface against the inward pull. The work required to increase the surface area by unit area is termed the *surface free energy*.

At the interface between two condensed phases, the dissimilar molecules in the adjacent layers facing each other have potential energies greater than those of similar molecules in the respective bulk phases. This is due to the fact that cohesive forces between like molecules tend to be stronger than adhesive forces between dissimilar molecules. Thus the interfacial tension is the force per unit length existing at the interface between two immiscible or partially miscible condensed phases and the interfacial free energy is the work required to increase the interface by unit area.

Adsorption Phenomena

Adsorption may be defined as the process of enrichment of one or more substances at a surface (1) or as the taking up of one substance at the surface of another (2). It can occur at any type of interface. However, in the context of pharmaceutical systems the interfaces where surfactant adsorption is important are the gas–liquid, liquid–liquid, gas–solid, and liquid–solid interfaces.

Adsorption at liquid–liquid and liquid–gas interfaces

Considering a system of two immiscible phases (e.g., heptane and water), a surface-active molecule that is adsorbed at the interface between the two liquids will tend to orient itself with its hydrophilic end toward the more polar liquid (water), and its hydrophobic end toward the less polar liquid (heptane). Thus the surfactant molecules replace water and/or heptane molecules of the original interface. The interaction across the interface is then between the hydrophilic group of the surfactant and the water molecules on one side of the interface, and between the hydrophobic group of surfactant and heptane on the other side of the interface. These interactions are much stronger than the original interactions between the unlike

Fig. 1 Schematic plot of surface or interfacial tension (γ) versus logarithm of the surfactant concentration (c).

molecules of heptane and water; therefore the interfacial tension is significantly reduced by the adsorption of surfactant at the interface (i.e., the inward pull for each phase at the interface is reduced).

Air consists of molecules that are mainly nonpolar. Surface tension reduction by surfactants at the air–aqueous interface occurs due to adsorption of surfactants at the interface, with the hydrophilic end of the surfactant oriented toward the liquid. The presence of the surfactant molecules reduces the net inward pull toward the bulk liquid, and therefore reduces the surface tension.

The effect of a surfactant on the lowering of surface tension is shown in Fig. 1. The surface tension is lowered even at low concentrations of surfactant. As the surfactant concentration is increased, the surface layer becomes saturated with surfactant molecules, and micelles form within the bulk liquid as an alternative way of shielding the hydrophobic portions of the surfactants from the aqueous environment; the surface tension tends to a constant value. Micelles are small aggregates of surfactant in which the surfactant molecules are arranged in such a way that the hydrophobic ends are shielded from the surrounding aqueous environment. The concentration at which micelles first appear in solution is termed the critical micelle concentration (CMC).

Adsorption at solid–liquid interfaces

Adsorption of surfactant from an aqueous solution onto a solid surface may involve specific chemical interaction between the surfactant (adsorbate) and the surface (adsorbent).

Common interactions that can occur (3) include:

1. An ion-exchange process
2. An ion-pairing interaction
3. Acid–base interaction via either hydrogen bonding between substrate and adsorbate or Lewis acid–Lewis base reaction
4. Adsorption by polarization of π electrons, where the adsorbate contains electron-rich aromatic nuclei and the adsorbent has strongly positive sites
5. Adsorption by dispersion forces, i.e., London–van der Waals dispersion forces acting between adsorbate and adsorbent
6. Hydrophobic bonding.

Contact Angles and the Wetting of Solids

A drop of liquid when placed on a flat, homogeneous solid surface, comes to equilibrium, assuming a shape which minimizes the total free energy of the system. The angle between the liquid and the solid is called the contact angle (θ), the angle being measured through the liquid (Fig. 2). The contact angle may be calculated if the surface and interfacial tensions are known from Young's equation given in Eq. 1 or 2.

$$\gamma_{SA} = \gamma_{SL} + \gamma_{LA} \cos \theta \quad (1)$$

or

$$\cos \theta = \frac{\gamma_{SA} - \gamma_{SL}}{\gamma_{LA}} \quad (2)$$

where γ_{LA} is the surface tension of the liquid, γ_{SL} is the interfacial tension existing between the solid and liquid phases, and γ_{SA} is the surface tension (or surface free energy) of the solid. If $\theta < 90^\circ$, wetting of the solid is said to take place. If $\theta > 90^\circ$, wetting does not take place.

Fig. 2 Contact angles. In (a), $\theta < 90^\circ$, and wetting of the solid occurs; in (b), $\theta > 90^\circ$, and wetting does not take place.

The term “wetting” refers to the displacement from a surface of one fluid by another. It is most commonly applied to the displacement of air from a liquid or solid surface by water or an aqueous solution. The term “wetting agent” is applied to any substance that increases the ability of water or an aqueous solution to displace air from a liquid or solid surface.

For good wetting, $\cos \theta$ should be as close as possible to 1; that is, θ should be as close as possible to 0. From Young's equation, it can be seen that if γ_{LA} or γ_{SL} was minimized, $\cos \theta$ would be maximized, and wetting would be promoted.

Contact angles of water on powders of pharmaceutical importance are usually measured by preparing disks of the powder by compression or melting. However, compaction may change the surface, so making the measured result of little relevance. Contact angles on finely divided solids can also be determined by packing the powder into a tube and measuring the penetration of liquids into the packing.

Three types of wetting phenomena have been described (4): adhesion wetting, spreading wetting, and immersional wetting.

The way in which a particular system behaves depends on the interfacial energies between the solid substrate and any contacting liquid, and between the liquid and the second fluid (air). By manipulating these factors, the wetting process can be controlled. This may be achieved by the use of surfactants.

Modification of the wetting process by the use of surfactants

The effect of surfactants on the wetting process is a result of their adsorption at various interfaces with a resulting alteration of interfacial tensions. As has been noted from Young's equation, the wetting process is promoted if either γ_{LA} or γ_{SL} or both are reduced with γ_{SA} remaining unchanged. Surfactants almost always cause a reduction in γ_{LA} , however, the same cannot be said for γ_{SL} and the effect on the interfacial tension depends on the nature of the adsorption. Thus the addition of a surface-active agent to the system does not always promote wetting, and spreading may in fact be made more difficult (4).

If adsorption of the surfactant molecules at the solid-liquid interface occurs in such a manner that they are oriented with their polar ends toward the substrate and hydrophobic ends toward the liquid, the wettability of an aqueous solution is reduced. This orientation of surfactant molecules at the surface occurs if they are adsorbing to ionic or polar substrates (ion-exchange or ion-pairing mechanism). However, at higher concentrations of surfactant, the surfactant ions adsorb by hydrophobic

interaction with the already adsorbed layer, thus exposing their hydrophilic ends to the solution in such a way that the surface becomes more readily wetted. Thus, the contact angle may first increase and subsequently decrease following the addition of more surfactant to a solution. In contrast, where adsorption occurs onto nonpolar surfaces by, for example, van der Waals attraction, the surfactant molecules are oriented with their hydrophilic groups toward the liquid, the hydrophilicity of the substrate is increased, and it becomes more wettable.

The adsorption of surfactants onto solid surfaces is important with respect to their detergent properties, their use as wetting agents in solid pharmaceutical dosage forms, and as stabilizers for suspension formulations. The mode of action of surfactants in each of these systems is discussed further below.

Micellization

As mentioned previously, surfactant molecules have the ability to form micelles in aqueous solution. These micelles are colloidal-sized clusters of molecules. Micellization is an alternative to interfacial adsorption for removing hydrophobic groups from contact with the aqueous environment, thereby reducing the free energy of the system. In micelles, the hydrophobic groups are directed toward the center of the surfactant aggregate. In cases where there is little distortion of the surrounding solvent by the hydrophobic group, there is little tendency for micellization to occur, such as in water when the hydrophobic group of the surfactant is short or in the case of nonaqueous solvents.

One of the most important applications of micellization in the context of pharmaceuticals is their ability to solubilize drugs of poor aqueous solubility.

Micelles are dynamic species; there is a constant rapid interchange of surfactant molecules between the micelle and the bulk solution. Micelles cannot, therefore, be regarded as rigid structures with a defined shape, although an average micellar shape may be considered.

The main types of micelles recognized (3) are:

1. Small spherical
2. Elongated cylindrical, rodlike micelles with hemispherical ends (prolate ellipsoids)
3. Large, flat lamellar micelles (disklike extended oblate spheroids)
4. Vesicles, more or less spherical structures, consisting of lamellar micelles arranged in one or more concentric spheres.

In nonaqueous solvents, surfactants may form “inverted micelles” where the hydrophilic heads of the surfactant

molecules are present in the center of the micelle with the hydrocarbon chains extending outward into the solvent. Dipole–dipole interactions hold the hydrophilic heads of the surfactant molecules together in the core, and in certain cases hydrogen bonding between head groups can also occur.

Micellar shape can be affected by changes in temperature, concentration and the presence of added electrolyte to the liquid phase. Changes in any of these factors may affect micellar size, shape, and aggregation number (number of surfactant monomers in the micelle).

Phase Behavior of Surfactants

Equilibrium phase structures

As the concentration of a surfactant solution is increased, structures of the types depicted in Fig. 3 may be encountered (5). At concentrations well above the CMC,

a more ordered structuring of the solution occurs. Two main types of liquid crystalline phases may be identified: the middle phase, M, exhibiting a hexagonal array of indefinitely long, mutually parallel rods; and the neat phase, G, with a lamellar structure. The liquid crystalline hexagonal phase, like the micellar phase, can exist either in a normal or reverse orientation. The order of phase structures formed upon increasing surfactant concentration generally follows a well defined sequence (Fig. 4) with a “mirror plane” through the lamellar phase in such a way that normal phase structures can be considered to be “oil-in-water” and the reverse structures to be “water-in-oil” (5).

Modified phase structures

In addition to the equilibrium phase structures mentioned above, nonequilibrium surfactant phase structures exist that are also finding applications in drug delivery. Vesicular forms of surfactants are generally formed by dispersing lamellar phases in an excess of water (or nonaqueous polar

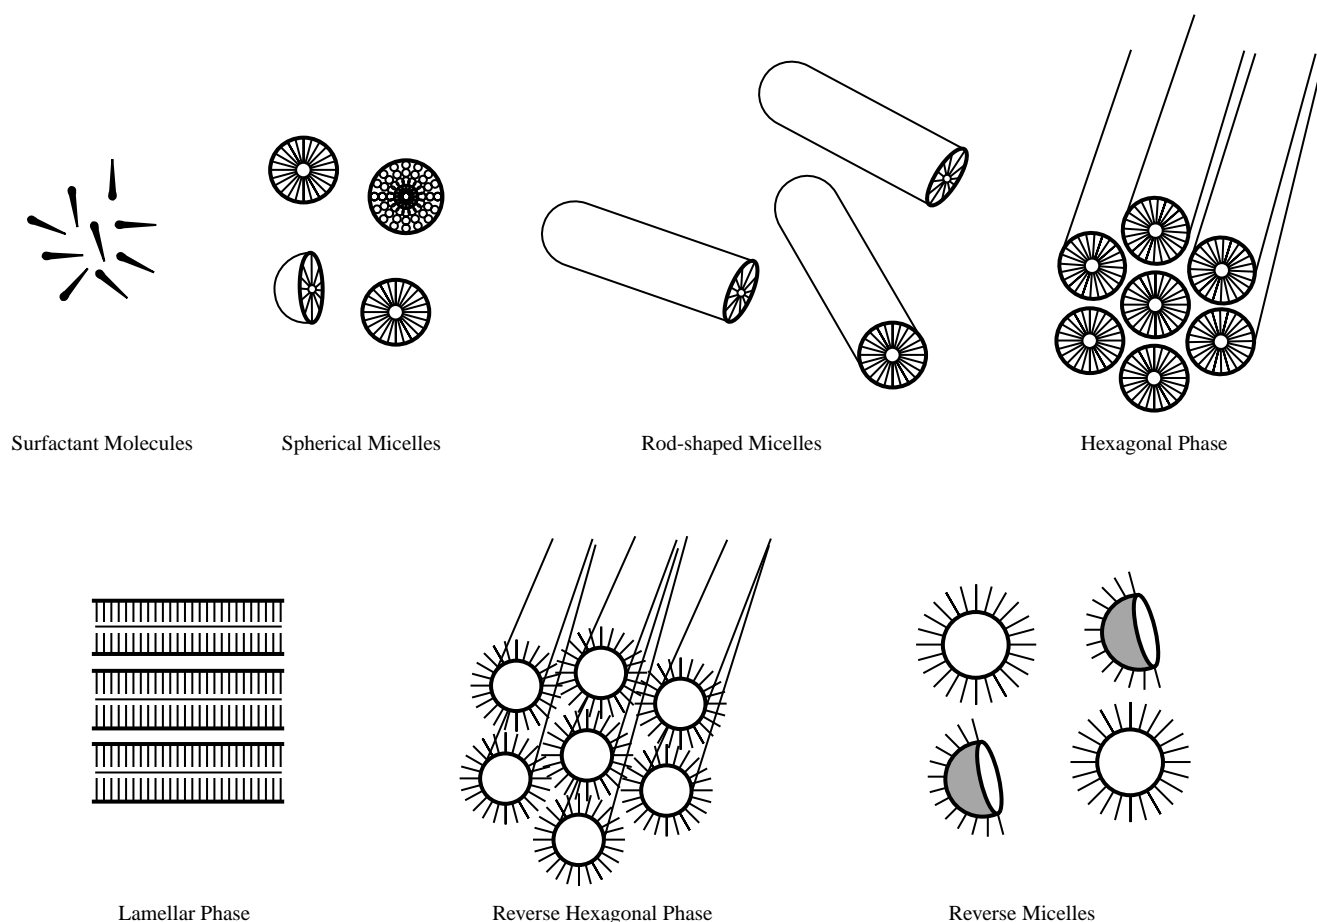

Fig. 3 Equilibrium phase structures of surfactant molecules. (From Lawrence, M.J. *Chem. Soc. Rev.* **1994**, 23 (6), 417–424, reproduced by permission of the Royal Society of Chemistry.)

Fig. 4 Idealized phase sequence in surfactant-water systems. (From Lawrence, M.J. *Chem. Soc. Rev.* **1994**, 23 (6), 417–424, reproduced by permission of the Royal Society of Chemistry.)

solvents such as ethylene glycol or dimethylformamide) or, in the case of reversed vesicles, in an excess of oil. With most surfactants, vesicles are nonequilibrium structures that will eventually re-equilibrate back into the lamellar phases from which they originated. Vesicles are structural analogs of liposomes (discussed later); they are approximately spherical structures and have the ability to “solubilize” both lipid soluble and water soluble agents.

Several of the phase structures produced by surfactants have potential as carriers and vehicles for drugs and also as targeting systems, used to direct the drug to a specific site in the body (5).

SURFACTANT CLASSIFICATION

Surfactant molecules may be classified based on the nature of the hydrophilic group within the molecule. The four main groups of surfactants are defined as follows:

1. *Anionic surfactants*, where the hydrophilic group carries a negative charge, such as carboxyl (RCOO^-), sulphonate (RSO_3^-) or sulphate (ROSO_3^-). Examples of pharmaceutical importance include potassium laurate, $\text{CH}_3(\text{CH}_2)_{10}\text{COO}^- \text{K}^+$, and sodium lauryl sulphate, $\text{CH}_3(\text{CH}_2)_{11}\text{SO}_4^- \text{Na}^+$.
2. *Cationic surfactants*, where the hydrophilic group carries a positive charge (e.g., quaternary ammonium halides, $\text{R}_4\text{N}^+\text{Cl}^-$). Examples of pharmaceutical importance include cetrимide, a mixture consisting mainly of tetradecyl (ca. 68%), dodecyl (ca. 22%), and hexadecyltrimethylammonium bromides (ca. 7%), as well as benzalkonium chloride, a mixture of alkylbenzyltrimethylammonium chlorides of the general formula $[\text{C}_6\text{H}_5\text{CH}_2\text{N}^+(\text{CH}_3)_2\text{R}]\text{Cl}^-$, where R represents a mixture of the alkyls from C_8H_{17} to $\text{C}_{18}\text{H}_{37}$.
3. *Ampholytic surfactants (also called zwitterionic surfactants)*, where the molecule contains, or can potentially contain, both a negative and a positive charge, (e.g., the sulfobetaines, $\text{RN}^+(\text{CH}_3)_2\text{CH}_2\text{CH}_2\text{SO}_3^-$). Examples of pharmaceutical importance include

N-Dodecyl-*N,N*-Dimethylbetaine, $\text{C}_{12}\text{H}_{25}\text{N}^+(\text{CH}_3)_2\text{CH}_2\text{COO}^-$.

4. *Nonionic surfactants*, where the hydrophile carries no charge but derives its water solubility from highly polar groups such as hydroxyl or polyoxyethylene ($\text{OCH}_2\text{CH}_2\text{O}$) groups. Examples of pharmaceutical importance include polyoxyethylated glycol monoethers (e.g. cetomacrogol), sorbitan esters (Spans[®]) and polysorbates (Tweens[®]).

Tables 1–4 in the article *Surfactants in Pharmaceutical Products and Systems* in Volume 14 of the first edition of this encyclopedia (6), together with the references cited therein, give listings of some of the surfactants most commonly used in pharmaceuticals, along with the purpose(s) for which they are usually employed.

SURFACTANT USES IN PHARMACEUTICAL PREPARATIONS

Because of their unique functional properties, surfactants find a wide range of uses in pharmaceutical preparations. These include, depending on the type of product, improving the solubility or stability of a drug in a liquid preparation, stabilizing and modifying the texture of a semisolid preparation, or altering the flow properties of a granulate, thus aiding in the processing of the final tablet dosage form. In addition to their use as excipients to improve the physical and chemical characteristics of the formulation, surfactants may be included to improve the efficacy or bioperformance of the product. The properties of surfactants are such that they can alter the thermodynamic activity, solubility, diffusion, disintegration, and dissolution rate of a drug. Each of these parameters influence the rate and extent of drug absorption. Furthermore, surfactants can exert direct effects on biological membranes thus altering drug transport across the membrane. The overall effect of inclusion of a surfactant in a pharmaceutical formulation is complex and may be beyond those initially intended.

Surfactants may reduce the effectiveness of antimicrobials or preservatives included in a formulation (7). They also have the capacity to damage biological membranes.

LIQUID SYSTEMS

Solutions

Surfactants as solubilizing agents

Solubilization can be defined as “the preparation of a thermodynamically stable isotropic solution of a substance normally insoluble or very slightly soluble in a given solvent by the introduction of an additional amphiphilic component or components” (4). The amphiphilic components (surfactants) must be introduced at a concentration at or above their critical micelle concentrations. Simple micellar systems (and reverse micellar) as well as liquid crystalline phases and vesicles referred to above are all capable of solubilization. In liquid crystalline phases and vesicles, a ternary system is formed on incorporation of the solubilize and thus these anisotropic systems are not strictly in accordance with the definition given above (4).

Solubilization by micelles

The location of a solubilized molecule in a micelle is determined primarily by the chemical structure of the solubilize. Solubilization can occur at a number of different sites in a micelle:

1. On the surface, at the micelle–solvent interface,
2. Between the hydrophilic head groups,
3. In the palisades layer, i.e., between the hydrophilic groups and the first few carbon atoms of the hydrophobic groups that comprise the outer regions of the micelle core,
4. More deeply in the palisades layer, and
5. In the micelle inner core.

In aqueous systems, nonpolar additives such as hydrocarbons tend to be intimately associated with the hydrocarbon core of the micelle. Polar and semipolar materials, such as fatty acids and alcohols are usually located in the palisades layer, the depth of penetration depending on the ratio of polar to nonpolar structures in the solubilize molecule.

In reverse micelles (formed in nonpolar solvent systems containing surfactant), polar additives may be solubilized in the core where a polar interaction of head groups occurs.

A preferred location of the solubilize molecule within the micelle is largely dictated by chemical structure. However, solubilized systems are dynamic and the location

of molecules within the micelle changes rapidly with time. Solubilization in surfactant aqueous systems above the critical micelle concentration offers one pathway for the formulation of poorly soluble drugs (7). From a quantitative point of view, the solubilization process above the CMC may be considered to involve a simple partition phenomenon between an aqueous and a micellar phase. Thus the relationship between surfactant concentration C_m and drug solubility C_{tot} is given by Eq. 3.

$$C_{tot} = C_s + PC_s C_m \quad (3)$$

where C_s is the drug solubility in the absence of surface-active agent and P is the distribution coefficient of drug between the micelle and bulk phases. A plot of C_{tot} versus C_m is linear with a slope of PC_s , which is the solubilizing capacity of the micelle (8).

The effect of altering the pH of the vehicle, in the case of a partly ionized drug will be to alter the apparent partition coefficient. Thus the effect of increasing the pH of a vehicle containing an acidic drug is to reduce the proportion of drug in the micellar phase. If the surfactant is a weak electrolyte, it may induce a concentration-dependent change in pH thus altering drug partitioning and solubility (9).

In general the solubilizing capacity for surfactants with the same hydrocarbon chain length increases in the order anionic < cationic < nonionic, the effect being attributed to a corresponding increase in the area per head group, leading to looser micelles with less dense hydrocarbon cores which can accommodate more solute.

The solubilizing capacity for a given surfactant system is a complex function of the physicochemical properties of the two components which, in turn, influence the location or sites where the drug is bound to the micelle. The molar volume of the solubilize together with its lipophilicity are important factors, the former reducing and the latter increasing solubilization (9).

Many pharmaceutical products contain a number of solutes potentially capable of being solubilized within the micellar phase. Thus competition can occur between solutes resulting in an altered solubilizing capacity. Furthermore, the addition of a second highly solubilized component to form a mixed micellar system may greatly alter the structure, size and solubilizing capacity of the system, thereby greatly enhancing drug solubility.

Solubilization has been used for many years in the formulation of phenolic antiseptic and disinfectant solutions. In the case of Cresol and Soap Solution (Lysol) and Chloroxylenol Solution B.P., soap micelles are used to solubilize the phenolic substances. The soap

(anionic surfactant) is formed by reaction of potassium hydroxide with a suitable oil such as linseed oil (in Cresol and Soap Solution) or castor oil (in Chloroxyleneol Solution). The solubilizing potential of surfactant solutions for hydrophobic species has also been exploited in the design of cholelitholytic solvents for gallstone dissolution with some limited success.

Stability of drugs in solubilized systems

Solubilization of a drug by incorporation into micelles may affect its stability (7). In the micelle, the molecular environment of the drug molecules changes their proximity and orientation with respect to each other, which may affect activity. In a micelle, the drug molecules may be protected from attacking species such as hydronium or hydroxide ions and the stability of the drug may be increased. The difference in environment between the micellar and bulk aqueous phases may be such that reaction rates may be radically changed by the transfer of solute to micelles. Micellar systems may be used to deliberately alter the rates and directions of chemical reactions (7).

AB block copolymer micelles

It is well known that block copolymers in a selective solvent (a good solvent for one block but a nonsolvent for the other) form a micellar structure through the association of the insoluble segments (10). In contrast with micelles formed from low molecular weight surfactants, block copolymer micelles dissociate slowly to free polymeric chains. They have a greater capacity for solubilizing aromatic molecules and express lower CMCs. The AB block copolymers are considered useful vehicles for hydrophobic drugs.

Only a few block copolymers form micellar structures in aqueous milieu. One example is a series of polyethylene oxide/polypropylene oxide/polyethylene oxide block copolymers known as Pluronics (tradename) or poloxamers. The poloxamers have been used widely in pharmaceuticals, particularly as emulsifiers for intravenous lipids (7). At low concentrations, poloxamer monomers are thought to form monomolecular micelles by a change in configuration in solution (7). At higher concentrations, aggregation of the monomolecular micelles occurs. The aggregates so formed show the ability to solubilize drugs and increase the stability of solubilized materials. Poloxamers have low toxicity and their solubilization capabilities might prove useful in the delivery of hydrophobic drugs, although multimolecular micelle formation with core-shell structure is uncertain under physiological conditions (11).

Other block copolymers have been prepared and studied as formulation adjuvants for hydrophobic drugs, e.g., poly(ethylene oxide)/poly(aspartic acid) and poly(ethylene oxide)/poly(β -benzyl-L-aspartate) block copolymers have been used with adriamycin (12, 13).

Suspensions

If a suspension is to be produced by a dispersion technique (as opposed to precipitation techniques), surfactants may be used in the formulation to aid dispersion of the solid particles in the liquid. This is particularly important if the powder is not readily wetted by the liquid vehicle. Surfactants can reduce the interfacial tension between the solid particles and the liquid vehicle. The advancing contact angle is reduced, and wetting of the solid particles promoted. Such a system is said to be deflocculated. The inclusion of a surface-active agent to improve powder wettability can often improve the bioavailability of the formulation.

The forces at the surface of a particle affect the degree of flocculation and agglomeration in a suspension. Particles dispersed in a liquid medium may become charged in one of two main ways. Ionic species present in solution may be adsorbed at the surface or, alternatively charges on the surface may arise due to ionization of groups (such as carboxyl groups for example) which may be located at the surface. The surface charge will influence the distribution of ions in the aqueous medium surrounding the solid particles. The result is the formation of what is known as an "electric double layer." If the surface charge is positive, immediately adjacent to the surface will be a region of tightly bound solvent molecules and negative counterions. Thus, the first layer is tightly bound, while the second layer (which still contains an excess of negative ions) is more diffuse (14). As two particles approach each other in aqueous medium, a weak attractive force exists just beyond the range of the double-layer-repulsive forces. This region is responsible for the particle interaction termed "flocculation."

Flocculated particles are weakly bonded, settle rapidly, do not form a cake and so are easily resuspended. For this reason it is frequently desirable to promote flocculation in a suspension.

The inclusion of surfactants in the formulation is one way of achieving what is known as "controlled flocculation." Surfactants can cause dispersed solids to flocculate by a number of different mechanisms (3). The first is where there is an electrostatic attraction of surfactant ions to oppositely charged sites on the particle surface, resulting in a lowering of the electrical energy

barrier to the close approach of two particles to each other. Flocculation may also occur by a bridging mechanism. A long (usually polymeric) surfactant molecule containing functional groups at various sites may adsorb onto sites on the surface of adjacent particles, holding the particles together in a loose arrangement. Alternatively if the surfactant molecules adsorb in such a manner that the molecule extends into the liquid phase, interaction of the extended portions of surfactant molecules adsorbed to different particles result in bridging of those particles.

Another method of employing surfactants to achieve flocculation is to first treat the particles with an ionic surfactant to disperse them. A readily soluble electrolyte is then added which has the effect of compressing the electrical double layer surrounding each particle, allowing flocculation to occur. Subsequent dilution of this type of system will redisperse it (due to a decrease in electrolyte concentration).

Emulsions

Emulsification is one of the most important applications of surface-active agents in pharmaceutical systems. The phenomenon has been extensively studied and many books and chapters of books have been devoted to the subject.

Macroemulsions are either oil in water (o/w) or water in oil (w/o). The type of emulsion formed depends largely on the emulsifying agent used; the process and relative proportions of the oil and water phases are less important. In general, o/w emulsions are produced by emulsifying agents that are more soluble in the water phase than in the oil phase, and w/o emulsions are produced by emulsifying agents that are more soluble in the oil phase. It is also possible to form a multiple emulsion. For example, a small water or aqueous solution droplet may be enclosed in a larger oil droplet which is itself dispersed in an aqueous phase. Such a system is referred to as a "water-in-oil-in-water" (w/o/w) emulsion. It is also possible to form an o/w/o emulsion.

Many medicinal agents which have an unpalatable taste or texture can be made more acceptable for oral administration when formulated as emulsions. Mineral-oil-based laxatives, oil soluble vitamins and high-fat nutritive preparations are frequently administered in the form of o/w emulsions. It has been shown that in some cases the absorption of drugs may be enhanced if formulated as emulsions (15). Emulsions (o/w) have also been used for the intravenous administration of lipid nutrients. Radiopaque emulsions have been used as diagnostic agents in X-ray examinations.

Emulsification is widely used in pharmaceutical products for external application such as lotions and creams, and in aerosol products to form foams. Semisolid emulsified formulations are discussed below.

Based on the size of the dispersed particles or droplets, emulsions may be classified (16) into

1. Macroemulsions, droplets $\sim 0.1-50\ \mu\text{m}$, opaque emulsions
2. Microemulsions, droplets $10-100\ \text{nm}$, transparent dispersions.

Stabilization of the dispersion of one immiscible liquid in another requires the addition of an emulsifying agent which is commonly a surfactant or a mixture of surfactants.

In the formation of an emulsion, one of the two immiscible liquids is broken up into droplets which are dispersed in the other liquid. The dispersion of one liquid in another immiscible liquid leads to a large increase in interfacial free energy because of the increase in the area of the interface. The emulsifying agent stabilises the emulsion by adsorbing at the liquid-liquid interface as an oriented interfacial film. This film reduces the interfacial tension between the liquids and also decreases the rate of coalescence of the dispersed droplets by forming mechanical, steric and/or electrical barriers around them.

A strong mechanical barrier lessens the chance of droplets coalescing on collision. For maximum mechanical stability, the interfacial film of the adsorbed surfactants should be close packed with strong lateral interactions. For this reason, a mixture of two or more surfactants is commonly used as the emulsifying agent, such as a combination of a water-soluble surfactant and an oil-soluble surfactant. In pharmaceutical (o/w) systems a mixture of a sorbitol ester (Span[®]) with a polyoxyethyleneated sorbitol ester (Tween[®]) is often used. The water soluble Tween tends to have a greater interaction with the aqueous phase, its hydrophilic group extending further into the water than that of the nonoxyethyleneated ester. This is believed to facilitate interaction of the hydrophobic groups of the molecules, as they can approach each other more closely in the interfacial film.

The interfacial film can also stabilize the emulsion by producing repulsive electrical forces between approaching droplets. This repulsion is due to surface charge on the droplets. The surface charge effect is believed to be important only in the case of o/w emulsions. The source of surface charge is the hydrophilic head of the surfactant molecules which is oriented toward the aqueous continuous phase. In emulsions containing ionic surfactant molecules, the charge on the disperse phase droplets

is due to the amphipathic ion. In the case of nonionic surfactants, the charge may arise either from adsorption of ions from the aqueous phase or from frictional contact between droplets and the aqueous phase. In the latter case, the phase with the higher dielectric constant is positively charged (3).

Microemulsions

Microemulsions consist of large or “swollen” micelles, containing an internal phase similar to that found in a solubilized solution (16). Unlike macroemulsions, they appear as clear, transparent solutions. They tend to be more thermodynamically stable than macroemulsions and can have essentially infinite lifetimes assuming no change in composition, temperature and pressure. This is in contrast to macroemulsions which, although they may remain stable for long periods of time, will ultimately undergo phase separation to attain a minimum in free energy. Microemulsions can generally be obtained by gentle mixing of the ingredients of the emulsion. In this respect, they differ from macroemulsions which require intense agitation for their formation. Microemulsions are usually prepared with more than one surfactant or using a mixture of surfactant and cosurfactant (e.g., a polar compound of intermediate chain length).

Microemulsions have been studied as drug delivery systems, in particular for topical and transdermal drug delivery (17, 18).

Microspherical particles prepared by emulsification processes

Emulsification–evaporation processes are widely used in the preparation of polymer based microspherical drug-loaded particulates. For example, hydrophobic drug-loaded PLA (polylactic acid) or PGLA (polylactide-co-glycolide) biodegradable microspheres are often prepared from emulsions containing a non aqueous dispersed phase of dichloromethane containing the drug and polymer in an aqueous continuous phase. For the preparation of hydrophilic drug loaded microspheres a double-emulsion process may be necessary. The nature of the surfactants used to stabilize the emulsion phases can greatly influence the size, size distribution, surface morphology, loading, drug release, and bioperformance of the final multiparticulate product.

Aerosols

Surfactants are found in both solution and suspension formulations of metered dose inhalers (MDIs). The most common surfactants found in pressurised aerosol preparations include sorbitan trioleate (Span 85), oleic acid,

and lecithins at concentrations of 0.1–2.0% (w/w). These agents are nonvolatile liquids which dissolve in the propellant blend. Their function in the formulation is to provide lubrication for the metering valves and, in the case of suspension formulations, to maintain the disperse nature of the drug.

The three surfactants commonly used in chlorofluorocarbon (CFC)-based MDI formulations are insoluble in the CFC-replacement propellants, hydrofluoroalkane (HFA) 134a and HFA 227. Possible formulation alternatives involve the use of an adjuvant such as ethanol to aid dissolution of the surfactant or a novel surfactant. Several companies have investigated novel materials among which are fluorosurfactants, polyoxyethylenes and drugs coated with surfactant (19).

Controlled flocculation in metered-dose aerosol suspensions

Controlled flocculation is a widely used technique for stabilizing suspended systems. The aim is to alter particle surface charge or to achieve particle separation via steric hindrance with the help of appropriate stabilizing excipients. However this is particularly difficult to achieve in nonpolar systems such as suspensions in CFC (or HFA) propellants. Controlled flocculation to optimise the stabilisation of MDIs has been recommended by Ranucci et al. (20) but disputed by Hickey et al. (21).

Liposomes

Liposomes are single- or multilayered phospholipids vesicles. They are roughly spherical in shape and consist of lipid bilayers alternating with aqueous regions.

Liposomes have shown potential as drug delivery systems. The exact location of a drug molecule in a liposome depends on its physicochemical composition and the composition of the lipids. Water soluble drugs may be included in the aqueous phase, and oil-soluble drugs may be added to the membrane-forming phospholipid. An extensive account of the pharmaceutical use of liposomes is found in the article “*Liposomes as Pharmaceutical Dosage Forms*,” by Y. Barenholz, and D.J.A., Crommelin, Volume 9 of the first edition of this encyclopedia (22).

SEMISOLID SYSTEMS

Surfactants are major constituents of pharmaceutical, cosmetic, and food semisolid formulations, many of which are emulsions, either oil in water (o/w) or water in oil (w/o). They are included for their stabilizing, wetting,

solubilizing, detergent and penetration-enhancing properties.

Water-in-oil emulsions traditionally contain surfactants of natural origin such as cholesterol, wool fat, wool alcohols, lanolin, divalent salts of fatty acids soaps, calcium oleate and/or synthetic agents of low hydrophilic-lipophilic balance (HLB) (indicating high lipophilicity), such as Spans (fatty acid esters of sorbitan). An example of such a product is Oily Cream B.P. which consists of a 1:1 mixture of wool alcohols and water.

Oil-in-water creams, for topical use, generally contain mixed emulsifiers/surfactants; one of which is a water soluble surfactant with a high HLB, the other being an amphiphile, usually a long chain fatty alcohol (e.g., of chain length C_{14} to C_{18}) or acid (e.g., palmitic or stearic). The water soluble surfactant may be anionic (e.g., sodium lauryl sulphate), cationic (e.g., cetrimide), or nonionic (e.g., cetomacrogol, Tweens).

These mixed-surfactant systems are used not only for their ability to form complex condensed films at the liquid-liquid interface, enhancing the stability of the emulsion, but also because of their ability to impart "body" to the product, resulting in a semisolid product rather than a liquid. Mixed emulsifiers control the consistency of a cream by forming a viscoelastic network throughout the continuous phase of the emulsion. The network results from the interaction of the mixed emulsifier with water, forming a liquid crystalline phase.

Foams

Emulsification is used in aerosol products to produce foams which are generally formulated as o/w emulsions. The liquified propellant forms the disperse phase of the emulsion, and the medication is usually in the aqueous continuous phase. On discharge from the pressurised container, the propellant vaporizes to form bubbles which remain trapped within the aqueous phase giving rise to a foam. These are referred to as "stable foam" products. Nonaqueous stable foams may also be formulated, where the water is replaced by various glycols such as polyethylene glycol. "Quick breaking foams" result when the propellant is in the external phase. The product is emitted as a foam and collapses into a liquid.

Biological Effects on Percutaneous Absorption

Surfactants—traditionally common constituents and stabilizers of topical vehicles, ranging from hydrophobic agents such as oleic acid to hydrophilic sodium lauryl

sulphate—have been tested as penetration enhancers to improve transdermal drug delivery. Ionic surfactants are thought to enhance transdermal absorption by disordering the lipid layer of the stratum corneum and by denaturation of keratin. The use of penetration enhancers in general, and surfactants in particular, in transdermal therapeutic systems has been reviewed by Walters (23).

SOLID DOSAGE FORMS

Surface-active agents have been widely shown to enhance drug dissolution rates. This may be due to wetting effects, resulting in increased surface area, effects on solubility and effective diffusion coefficient or a combination of effects. Consequently surfactants have been included in tablet and capsule formulations to improve wetting and deaggregation of drug particles and thus increase the surface area of particles available for dissolution.

This wetting effect is found to be operative at concentrations below the CMC. The effect of surfactants on the dissolution of solids is complex. In addition to effects on the available surface area, surfactants in concentrations above the CMC can increase drug solubility and hence the effective concentration gradient. However they also reduce the effective rate of drug diffusion as a consequence of drug solubilization within micelles. Models to quantify the effect of surfactant concentration on drug dissolution have been developed (24). For solids whose dissolution is under significant surface control, surfactants may further influence the dissolution process. In this regard the enhancing effect of surfactants on the dissolution rate of cholesterol has been widely studied (25).

Hard Gelatin Capsules and Tablets

Wetting agents

Surfactants are used in capsule (26) and tablet formulations as wetting agents to aid dissolution.

Lubricants, anti-adherents, and glidants

The primary function of tablet lubricants is to reduce the friction arising at the interface of tablet and die walls during compression and ejection. Lubricants also possess antiadherent (prevention of sticking to the punch and, to a lesser extent, to the die wall) and glidant (improvement of flow characteristics of powders or granulates) characteristics and are useful in the processing of hard gelatin capsules.

Magnesium stearate is used extensively as a lubricant in tablet manufacture. It is an example of a “boundary lubricant,” that is, the polar regions of the molecule adhere to the metal surface of the die wall (in tablet manufacture). Adsorption of magnesium stearate to the powder or granule surfaces also prevents agglomeration of the feed material and aids flow.

Lubricants may be classified as water-soluble or water-insoluble. The latter are generally more effective than water-soluble lubricants and can be used at a lower concentration (27). Common water-insoluble lubricants (which are surfactants) include magnesium stearate, calcium stearate, sodium stearate, and stearic acid; water-soluble lubricants include sodium lauryl sulphate and magnesium lauryl sulphate.

Sodium lauryl sulphate is used in the production of hard gelatin capsules where it is added to the gelatin solution during the preparation stage. The stainless steel molds are lubricated prior to dipping into the gelatin solution and sodium lauryl sulphate is added to reduce the surface tension of the mix and cause the mold pins to wet more uniformly (28).

Solid Dispersion Systems

The bioavailability of hydrophobic drugs can be increased by strategies designed to enhance the dissolution rate of the drug. This has been achieved in many cases by forming a solid dispersion of the drug in a suitable carrier, often a hydrophilic polymer such as polyethylene glycol (PEG) or polyvinylpyrrolidone (PVP). The drug is dispersed in the carrier by coprecipitation from a suitable solution containing both drug and carrier, by melting both components together, or by some other process involving a phase change. By using relatively high concentrations of carrier and a rapid precipitating process, the drug may form as an amorphous or molecularly dispersed high energy phase in the carrier. A number of workers have used surfactants as the carrier material to achieve this enhanced dissolution effect. Among the surfactants employed are polyoxyethylene stearate, Renex 650, poloxamer 188, Texafor AIP deoxycholic acid, and Tweens and Spans. Surfactants have also been added to conventional drug-polymer solid dispersions to further improve drug release properties. Sjökvist et al. (29) found that the incorporation of sodium dodecyl sulphate (1–2%) in griseofulvin (3–10%)-PEG solid dispersions eliminated any traces of crystalline drug, griseofulvin being present as a solid solution. Other three-component solid dispersions containing surfactants have also been reported such as Tween 20-Griseofulvin-PEG and Tween 20-Oxodipine-

PEG (30). Problems have been reported however as to the physical stability of surfactant containing systems, dissolution rates decreasing over a 12-month period (31).

Matrix Systems

Drug release from nondisintegrating inert matrices, fabricated from hydrophobic carriers such as polyethylene, is improved by the presence of surfactants in the dissolution medium. Drug release was shown to be a function of the pore size distribution of the matrix and the permeation pressure of the release media defined by its surface tension and contact angle. Inclusion of dioctyl sodium succinate, which reduced the contact angle below 90°, greatly enhanced drug release; increasing the concentration of polysorbate in the range of 0.001–0.1% had the same effect (32). Surfactants have also been included in matrix-type drug delivery systems to aid penetration of the dissolution medium thus increasing the rate and extent of drug release.

Suppositories

Several nonionic surface-active materials have been developed as suppositories vehicles. Many of these bases, known as water-dispersible bases, can be used for the formulation of both water-soluble and oil-soluble drugs (33). The surfactants most commonly used are the polyoxyethylene sorbitan fatty acid esters (Tweens), the polyoxyethylene stearates, and the sorbitan fatty acid esters (Spans). These surfactants may be used alone, blended, or with other suppository base materials to yield a wide range of melting points and consistencies.

Surface-active agents are widely used in combination with other suppository bases. The inclusion of these agents in the formulation may improve the wetting and water-absorption properties of the suppository. In addition, emulsifying surfactants help to keep insoluble substances suspended in a fatty base suppository (33).

The inclusion of a surfactant in the suppository formulation may enhance the rectal absorption of drugs. The effect has been attributed to the formation of mixed micelles. It has been suggested that the presence of the micelle facilitates the incorporation of the lipid component of the mixed micelle into the biological membrane. This lipid then enhances the fluidity and permeability of the membrane to the poorly absorbed drug. It appears that the colorectal mucous membrane is more sensitive to the effects of mixed micelles than the gastrointestinal membrane of the small intestine.

Surfactant Influence on Drug Absorption from the Gastrointestinal Tract

In the context of oral dosage forms containing surfactants, these agents may play a role in reducing the rate of gastric emptying and retarding the movement of drug to the absorption site by increasing the viscosity of the formulation. This is thought to be especially true of polyoxyethylene derivatives. Bile salts, which are physiological surfactants, have been shown to affect the rate of gastric emptying. The presence of bile salts in the stomach has also been shown to affect ionic movement across the gastric mucosa, thus increasing the movement of hydrogen and chloride ions out of the lumen.

Surfactants may also affect the rate and extent of drug absorption by exerting an influence on the permeability of the biomembrane. Competitive binding of the surfactant to the membrane protein is considered to be partially responsible for enhanced drug absorption in many cases. Alternatively, the enhancement may be due to allosteric rearrangement of the membrane protein which is triggered by the binding of one or more permeating species.

Nakanishi et al. (34) studied the effect of a range of surfactants on the rectal absorption of sulphaguanidine and found absorption to be increased. The increase was associated with histological changes in rectal membrane, increasing the rectal permeability. The same authors found that surfactants such as sodium deoxycholate and sodium dodecyl sulphate used together with the chelating agent EDTA could increase the rectal absorption of macromolecules such as inulin, insulin, and albumin.

The membrane effects of surfactants are explained by a combination of membrane-surfactant binding, disruption of membranes through solubilization into lipoproteins, proteins, and mixed micelles, protein-protein interactions, and selective solubilization of some membrane components by the surfactant. The structure of the surfactant may play a role in determining the range and extent of the influence of a particular surfactant on drug absorption. It appears that the greatest effect is achieved by molecules having a C12–C16 hydrocarbon chain, polyoxyethylene chain lengths between 10 and 20, and molecular areas between 1.0 and 1.6 nm² (4). These effects, in the case of drugs of low aqueous solubility, are in addition to the higher absorption rate, arising from an increase in drug solubility (35, 36).

Surfactants, at high concentrations, exhibit some toxicity and have the ability in many cases to disrupt a membrane. Both ionic and nonionic surfactants have been shown to assist the breakdown of the mucous layer covering the epithelium and at high concentrations are thought to interfere with the membrane itself, which may

lead to disruption of membrane metabolism, particularly with regard to enzyme systems associated with the membrane. Adverse reactions to drug formulation agents including surfactants have been reviewed by Weiner and Bernstein (37).

DIRECT ACTIONS OF SURFACTANTS

Detergents

Detergents are surfactants that are used for the removal of foreign matter from a solid surface. The process involves many of the actions specific to surfactant molecules. The surfactant requires good wetting properties to ensure good contact with the solid surface. It must also have the ability to remove dirt into the bulk liquid. This is achieved by a lowering the dirt-liquid and solid-liquid interfacial tensions, thus reducing the work of adhesion between the dirt and the solid and enabling the dirt to be readily detached. Once detached, adsorption of surfactant at the dirt particle surface prevents deposition, allowing the dirt to be washed away. If the dirt is oily it may be emulsified or solubilized by the surfactant.

Antimicrobial Activity

Significant antimicrobial effects have been associated with cationic surfactants, in particular the quaternary compounds. The action mechanism of quaternary surfactants involves disruption of the cell membrane, protein denaturation, and enzyme inhibition. Quaternary compounds are able to lyse cells at relatively low concentration, resulting in leakage of cell contents into the surrounding medium. Quaternary ammonium and some phosphonium surfactants are used as topical disinfectants in commercial dermatological products, in surgical hand scrubs, and in the irrigation of skin wounds. The most commonly used quaternary compounds employed for their antimicrobial effects are cetylpyridinium chloride, benzalkonium chloride, benzethonium chloride and cetyltrimethylammonium bromide (38). Other surfactants, containing more than one quaternary (or positively ionizable group) are among the most active substances known in terms of antimicrobial activity. Included in this group are dequalinium acetate and chlorhexidine gluconate which have been used in throat lozenges and mouthwashes. The lysis of cells can also occur in the presence of anionic surfactants, although these are in general weaker in their antimicrobial activity. A wide range of anionics, in particular sodium lauryl sulphate and its homologs, finds wide application in mouthwashes (38).

Respiratory Distress Syndrome (RDS)

In 1959, surfactant deficiency was identified as the major pathogenic factor in respiratory distress syndrome in infants (39). Pulmonary surfactant is a complex mixture of phospholipids, neutral lipids, and specific proteins which spread as a monolayer at the air-liquid interfaces of the lung and lower surface tension at end-expiration thus preventing alveolar collapse. If the amount or quality of endogenous surfactant is inadequate, inspiratory pressure and the work of breathing must increase in order to re-expand the alveoli with each breath and permit adequate gas exchange. As the infant grows tired, progressive respiratory failure occurs.

Phosphatidylcholine is the major component of endogenous surfactant, constituting about 60% of total phospholipids, and dipalmitoylphosphatidylcholine (DPPC) is the primary surface-tension lowering phospholipid.

The surfactant replacement therapy treatment used may be either "natural" or "artificial." Natural surfactants are derived from bovine or porcine animal lungs or human amniotic fluid. Synthetic or artificial surfactants are composed of DPPC and spreading agents such as unsaturated phosphatidylglycerol or tyloxapol and hexadecanol (40).

NATURALLY OCCURRING SURFACTANTS

Of the naturally occurring surfactants, the bile salts and phospholipids are of particular importance.

Phospholipids

The phospholipids are widely found in biological membranes and can be used as emulsifiers especially for intravenous fat emulsions, and as a key component of liposomes. The elucidation of factors governing the solubilization of drugs in phospholipid dispersions can provide some clues as to the biological role of interactions with lipid systems *in vivo* (4). Phospholipids have been discussed above and in reference (22) in the context of liposomes.

Bile Salts

Bile salts are carboxylic acids (C22–C28) with a cyclopentenophenanthrene nucleus containing a branched chain of 3–9 carbon atoms ending in a carboxyl group. Structurally they form micelles which are different from the conventional spherical micelles

synonymous with amphiphiles having a distinct hydrocarbon chain. The hydrophobic feature of the bile salts is associated with one surface of the steroid nucleus, and consequently intermolecular association is much more restricted. Primary and secondary micelles have been proposed, the former consisting of two to four molecules, the latter being composed of aggregates of the primary micelles. The CMC is less distinct and is highly dependent on the structure of the specific bile salt, in particular the number of hydroxy groups and their orientation.

Many studies have been completed in order to assess the effect of bile salts on the bioavailability of poorly soluble drugs. Bile salts for example, have been shown to enhance the absorption of sulphaguanidine and urogastone. Bile salts may also play a role in enhancing the transport of a compound from the lumen of the intestine to the systemic circulation. Such absorption involves overcoming the resistance of the aqueous boundary layer and the membrane epithelium to the passage of the drug.

Bile salts readily form mixed micelles with lipid-like molecules such as lecithins or fatty acids. These mixed micelles are structurally very different from the simple micelles and generally have a much greater solubilizing capacity for hydrophobic molecules, both biological and synthetic. The solubility of DDT, a nonpolar, water insoluble molecule, for example, in bile salt micellar solution can be increased to a far greater extent by the addition of unsaturated long chain fatty acids, probably because of mixed micelle formation.

Saponins

Saponins are glycosides found in certain plants which are characterized by their property of producing a frothing aqueous solution. The term "saponin" is derived from the Latin "sapo" meaning soap. Plant materials containing saponins have been used for a long time in many parts of the world for their detergent properties, for example, in Europe, the root of *Saponaria officinalis* and in South America the bark of *Quillaja saponaria* (41).

The saponin structure is either of the steroidal (commonly tetracyclic triterpenoids) or pentacyclic triterpenoid type. Triterpenoid saponins are found, for example in Quillaia bark and in liquorice root. Quillaia B.P. is defined as the dried inner part of the bark of *Quillaja saponaria* and other species of *Quillaja* and is used as an emulsifying agent. Liquorice, the root of which also contains triterpenoid saponins, has long been used in pharmacy as a flavoring agent, demulcent, and mild expectorant.

Iscoms

Iscoms (Immune-stimulating complexes) are stable complexes of cholesterol, phospholipid, and Quil A (derived from *Quillaja saponaria*) in size ranges from 40 to 100 nm. They are promising carriers for antigens in subunit vaccines. Iscoms are considered to be multi-micellar structures, shaped and stabilized by hydrophobic interactions, electrostatic repulsion, steric factors and possibly hydrogen bonds (42). Protection has been achieved after immunization with iscom-based vaccines, against viruses like the Epstein–Barr virus (43) and the measles virus (44).

SURFACE ACTIVITY OF DRUGS

A large number of drug molecules exhibit surface activity, that is, they tend to accumulate at interfaces, depress surface tension and associate to form aggregates in solution. Although the hydrophobic groups of most drugs are aromatic, they still behave like typical surfactants (which possess flexible hydrophobic chains), inasmuch as these aromatic groups have a high degree of flexibility. (Drugs that exhibit association characteristics typical of surface active agents and may reduce surface tension are reviewed in Ref. 4.)

Most of the drugs form micelles at concentrations that they do not attain in vivo. It is therefore their surface activity, rather than their self-association tendency which is more important biologically. Surface-active drugs will tend to bind hydrophobically to proteins and other macromolecules and to associate with other amphipathic substances such as bile salts, phospholipids, and receptors. As with other surface-active agents, surface-active drugs may interact directly with biological membranes. The possible biological implications of surface activity is discussed by Attwood and Florence (4) in relation to the phenothiazine tranquillisers and local anesthetics.

SUSPENSIONS

Robert A. Nash

Consultant, Mahwah, New Jersey, U.S.A.

INTRODUCTION

A suspension is a particular class or type of dispersion or dispersed system in which the internal or suspended phase is dispersed uniformly by mechanical agitation throughout the external phase (called the suspending medium or vehicle). The internal phase, consisting of a homogeneous or heterogeneous distribution of solid particles having a specific size range, is maintained uniformly throughout the suspending vehicle with the aid of a single or a particular combination of suspending agent(s). In addition, unlike in a solution, the suspended particles exhibit a minimum degree of solubility in the external phase. In a colloidal suspension, the solids are less than about 1 μm in size. In a coarse suspension, they are larger than about 1 μm . The practical upper limit for individual suspendable solid particles in coarse suspensions is approximately 50–75 μm . When one or more types of solid particles that constitute the internal phase are pharmaceutically useful and/or physiologically active, the system is known as a pharmaceutical suspension.

In an emulsion, the particles of the internal phase are spherical or liquid droplets that are dispersed throughout a liquid external phase. Even though the particles may be liquid only at elevated temperatures (50–80°C) and semisolid or rigid at room temperature, as long as they appear spherical on careful microscopic examination, they are generally considered to be emulsified rather than suspended. Thus, a clue to the presence of a suspended particle is its lack of sphericity or its definitive lattice structure. Exceptions to this general rule are spherical microspheres and related spherical solid microparticles.

CLASSIFICATION

Martin and Bustamante (1) list three general classes of pharmaceutical suspensions: orally administered (sometimes referred to as mixtures), externally applied (topical lotions), and injectable (parenteral).

Oral Suspensions

The solids content of an oral suspension may vary considerably. For example, antibiotic preparations may contain 125–500 mg of active solid material in a 5-ml (teaspoonful) dose, whereas a drop concentrate may provide the same amount of insoluble drug in a 1- or 2-mL dose. Antacids and radiopaque suspensions contain relatively high amounts of suspended material for oral administration. The vehicle may be a syrup, a sorbitol solution, or a gum-thickened, water-containing artificial sweetener because in addition to ingredients, safety, taste, and mouthfeel are important formulation considerations. In the case of limited shelf life (low chemical stability of the insoluble drug), the dosage form may be prepared as a dry granulation or powder mixture that is reconstituted with water prior to use.

Topical Suspensions

Historically, the externally applied “shake lotion” is the oldest example of a pharmaceutical suspension. Calamine Lotion USP, as well as other dermatological preparations, is closely associated with the technical development of the pharmaceutical suspension (2). Because safety and toxicity considerations are most readily dealt with in terms of dermatological acceptability, many useful suspending agents were first introduced in topical formulations (3). In addition, the protective action and cosmetic properties of topical lotions usually require the use of high concentrations of the dispersed phase, often in excess of 20%. Therefore, topical lotions represent the best example of suspensions that exhibit low settling rates (4). Various pharmaceutical vehicles have been used in the preparation of topical lotions, including diluted oil-in-water or water-in-oil emulsion bases, dermatological pastes, magmas, and clay suspensions.

Parenteral Suspensions

The solids content of parenteral suspensions is usually between 0.5 and 5.0%, except for insoluble forms of penicillin, in which concentrations of the antibiotic may exceed 30%. These sterile preparations are designed for

intramuscular, intradermal, intra-lesional, intra-articular, or subcutaneous administration. The viscosity of a parenteral suspension should be low enough to facilitate injection. Common vehicles for parenteral suspensions include preserved 0.9% saline solution or a parenterally acceptable vegetable oil. The primary factor governing the selection of injectable ingredients is safety. Ophthalmic suspensions that are instilled into the eye must be prepared in a sterile manner. The vehicle is employed is essentially isotonic and aqueous in composition.

UTILITY OF SUSPENSIONS

A suspension is often chosen as pharmaceutical dosage form for drugs insoluble in water and aqueous fluids at the dosage required for administration and when attempts to solubilize the drug would compromise stability and safety. For oral administration, the taste of a bitter or unpleasant drug can often be masked by choosing an insoluble form of the active drug.

An aqueous suspension is a useful oral dosage form for administering insoluble or poorly soluble drugs. The large surface area of the dispersed drug particles often facilitate absorption. Unlike drug particles contained in tablets or capsules, the dissolution of drug particles in suspension and subsequent absorption commence upon dilution in gastrointestinal fluids. Finely divided particles dissolve faster and have higher relative solubilities than do similar macroparticles.

The parenteral suspension is an ideal dosage form for prolonged or “depot” release. In the administration of a drug as an aqueous or oleaginous suspension into subcutaneous or muscular tissue, the drug is deposited at the injection site. The depot acts as a reservoir, slowly releasing drug at a rate related to both the intrinsic aqueous solubility of the drug form and the type of suspending vehicle, either aqueous or oily for the purpose of maintaining prolonged systemic absorption of the drug from the injection site.

HYDROPHILIC/HYDROPHOBIC SOLIDS

Insoluble solids, regardless of particle size, that have a relatively low interfacial tension and are readily wetted by water are called *hydrophilic* solids. These solids include clays (bentonite, kaolin, talc, magnesium aluminum silicate); bismuth salts, barium sulfate, carbonates, hydroxides, or oxides of calcium, magnesium, zinc, and aluminum; and titanium dioxide. The hydrophilicity of a powder surface can be investigated with the help of

moisture absorption studies in which the solid particles are exposed to varying relative humidities. Insoluble powders that absorb moisture below relative humidities of 70–80% at room temperature are said to be hydrophilic solids.

Fine insoluble solids that are not easily wetted by water and have a relatively high interfacial tension are referred to as *hydrophobic* solids. These include a large number of low-density organic materials and pharmaceutical substances, such as charcoal and sulfur. The hydrophobic nature of the latter group is accentuated by entrapped air adsorbed on the surface of these particles. Hydrophobic materials may be wetted by oils and semipolar liquids and are called lipophilic solids; conversely, hydrophilic materials behave like lipophobic solids in oils.

Hydrophilic solids can be suspended easily in water without the aid of a water-dispersible surfactant or wetting agent, and conversely hydrophobic solids can be suspended in oils and nonpolar vehicles without the use of lipid-soluble surfactants. The crystal density of hydrophilic solids usually ranges from 1.5 to 6.9 g/cm³, whereas the crystal density of hydrophobic solids usually ranges from 0.9 to 2.2 g/cm³.

PARTICLE SIZE CONSIDERATIONS

The mean particle diameter and the particle size distributions of suspended insoluble drugs are important considerations in formulating stable pharmaceutical suspensions. Hiestand (5) defines the lower limit of coarse suspensions as those containing particles larger than 0.1 μm . Except for a number of clays, oxides, charcoal, and pigments, the average particle size of most drugs and pharmaceutical rarely falls below 1 μm . Although most submicron inorganic excipients appear to behave like hydrophilic solids, most insoluble drugs and pharmaceutical excipients are usually soft, organic, essentially crystalline hydrophobic solids ranging in particle size from several microns to several hundred or more.

Drug particle size is an important factor influencing product appearance, settling rates, drug solubility, in vivo absorption, resuspendability, and overall stability of pharmaceutical suspensions. Insoluble drug particles are seldom uniform spheres or cubes, even after size reduction and classification. Wide distributions in particle size often lead to high-density suspensions. Systems with widely differing particle shapes (plates, needles, filaments, and prisms) frequently produce low-density slurries. The growth over time of unprotected, slightly soluble drug solids and changes in their particle size distribution in suspension are

a serious problem. Crystal growth of particles is usually attributed to one or more of the following mechanisms:

- “Oswalt ripening” or the growth of large particles at the expense of smaller ones, because of a difference in solubility rates of different size particles. For example, the increase in the solubility rate of a 0.2- μm particle, is 13%. For a 2- μm particle, it is 1%, and for particles above 20 μm , it is negligible.
- Crystal growth due to temperature fluctuations on storage is of minor importance, unless suspensions are subjected to temperature variations of 20°C or more.
- A polymorphic form may change to another more stable crystalline form; changes in crystal habit may be related to the degree of solvation or hydration.
- Crystal growth may also arise when the more energetic amorphous or glassy forms of a drug exhibit significantly higher initial solubility in water than the corresponding crystalline forms.
- Size reduction by crushing and grinding can produce particles whose different surfaces exhibit high and low solubility rates. This effect can be related to differences in the free surface energy introduced during comminution (grinding).

Crystal growth and changes in particle size distribution can generally be controlled by employing one or several of the following procedures and techniques.

1. Selection of particles with a narrow range of particle sizes, such as microcrystals between 1 and 10 μm .
2. Selection of a stable crystalline drug form that usually exhibits lower solubility in water. The crystalline form that is physically most stable usually has the highest melting point.
3. High-energy milling should not be used during particle size reduction. Microcrystals are best formed by controlled precipitation techniques or shock cooling.
4. A water-dispersible surfactant wetting agent dissipates the free surface energy of particles by reducing the interfacial tension between the solid and the suspending vehicle.
5. A protective colloid, such as gelatin, gum, or a cellulosic derivative, is used to form a film barrier around the particles, inhibiting dissolution and subsequent crystal growth.
6. The viscosity of the suspending vehicle is increased to retard particle dissolution and subsequent crystal growth.
7. Temperature extremes during product storage (freeze–thaw conditioning) must not occur.

8. Supersaturation favors the formation of needlelike crystals and should be avoided.
9. Rapid or shock cooling and high agitation favor the formation of thin, small crystals and should be avoided. Slow crystallization by evaporation yields compact crystals.
10. Experimentation with different crystallizing solvents is recommended to change crystal size and shape.
11. Impurities and foreign substances during crystallization affect the reproducibility and aggregation potential of many drug particle systems.
12. Constant crystallizing conditions are essential. Batch-to-batch variation in crystal size and shape is often associated with poor control of processing and crystallization procedures.

Variations in assay results can be avoided by the preparation of homogeneous, well-mixed, or nonsettling fine particle suspensions (size 1–10 μm). Particle size reduction results in slow, more uniform settling rates. The bioavailability of drugs is improved by reducing the size of suspension particles. Furthermore, drug particles smaller than 20 μm produce less pain and tissue irritation when injected parenterally. However, fine particles may have a deleterious effect on chemical stability because of their high dissolution rate.

Particle Size Reduction

Drug solids are easy to grind. Reduction to a particle size of about 50–75 μm usually produces a free-flowing powder. Solids containing particles smaller than 50 μm tend to aggregate or agglomerate in the dry state. Furthermore, below 10–50 μm , the increased free surface energy, as evidenced by the cohesion of small particles, becomes a factor interfering with further size reduction. The powder may become damp, especially if there is a tendency to attract moisture. Material tends to “ball up,” which indicates that the agglomerated masses are larger than the individual particles contained within.

As the pores between powder particles become smaller with decreasing particle size, increases in surface area facilitate liquid penetration. Aggregates behave like hydrophobic solids, entrapping air and becoming difficult to wet.

The most efficient method of producing fine particles is by dry milling prior to manufacture of the suspension. Dispersion equipment, such as colloid mills or homogenizers are normally used to wet-mill finished suspensions to break up poorly wetted fine particle aggregates or agglomerates. Among the several methods of producing small, reasonably uniform drug particles are micropulverization, fluid energy grinding, controlled precipitation, and

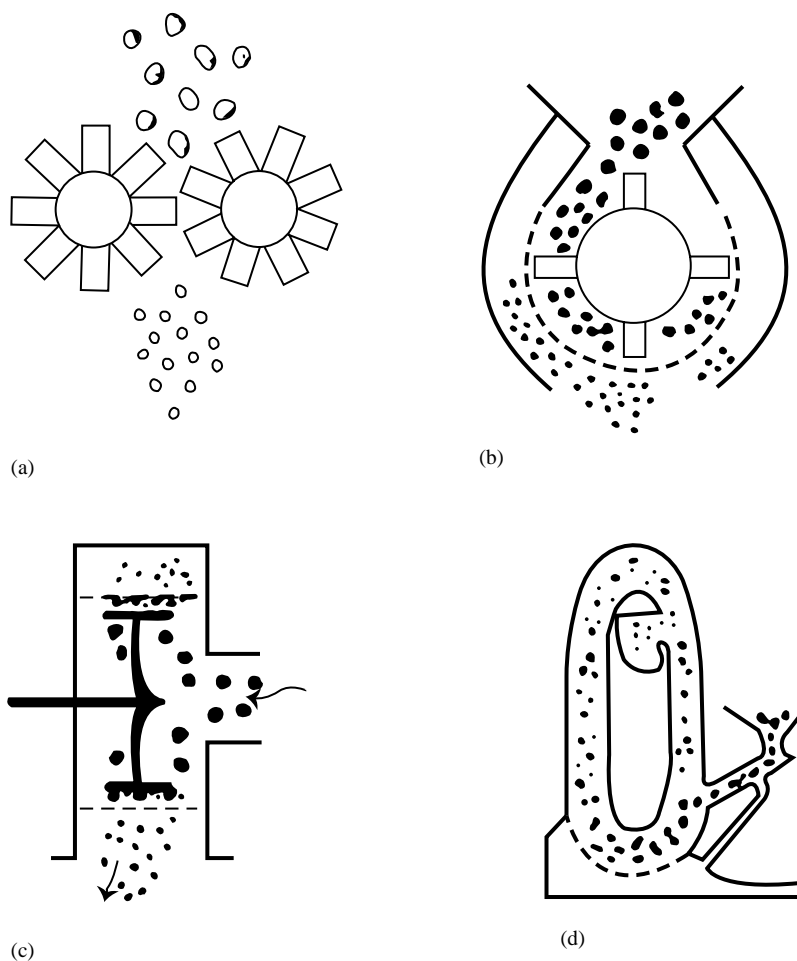

Fig. 1 The four basic types of size reduction equipment used to produce fine solid particles: (a) Crushers and shredders. (b) Hammermills. (c) Colloid mills. (d) Fluid energy mills.

spray drying. Figure 1 illustrates the four basic types of size reduction equipment used in the pharmaceutical industry to produce fine powder particles.

Micropulverization

Micropulverization is one of the most rapid, convenient, and inexpensive methods of producing fine drug powders. The milling equipment includes hammermills, micropulverizers, universal mills, end-runner mills, and ball mills. Micropulverizers are highspeed attrition or impact mills specially adapted for fine grinding. Some mills are fitted with classifiers to facilitate particle separation by centrifugation. Because ultrafine particles smaller than $10\text{ }\mu\text{m}$ are rarely produced, buildup of electrostatic charge on the surface of milled powder is encountered only occasionally. The main disadvantage of micropulverization is the large distribution of particle sizes

produced, normally in the range of $10\text{--}50\text{ }\mu\text{m}$ or higher. Nevertheless, these powders are satisfactory for the preparation of most oral and topical suspensions.

Fluid energy grinding

The process of fluid energy grinding, also referred to as jet milling or micronizing, is the most effective method for reducing particles below $10\text{ }\mu\text{m}$. The ultrafine particles are produced by the shearing action of high-velocity streams of compressed air on particles in a confined space. The main disadvantage of fluid energy grinding is the high electrostatic charge built up on the surfaces of the milled powder, which makes powder classification and collection exceedingly difficult. However, because it is important that a majority of drug particles in parenteral suspensions are below $10\text{ }\mu\text{m}$, fluid energy grinding is the most convenient method for their production.

Controlled crystallization

A solvent that dissolves a solid readily at room temperature may serve as a crystallizing medium when mixed with another solvent in which the compound is only sparingly soluble. A solution that is nearly saturated at a temperature about 10°C below the boiling point of the solvent combination is prepared in a temperature ranging between 60 and 150°C. Separation of microcrystals from such hot concentrated solutions is commonly induced by cooling and stirring. However, when supersaturation is obtained by agitation and shock cooling of the hot solution and through the rapid introduction of another cold miscible solvent in which the drug is only sparingly soluble, formation of minute crystalline particles (nucleates) proceeds without appreciable crystal growth, and uniform microcrystals of the drug are thus obtained. In addition, ultrasonic methods have been used during shock cooling to promote microcrystal formation.

Spray drying

Particles of microcrystalline size can also be obtained by spray-drying procedures, resulting in a porous, free-flowing, easily wetted, essentially monodispersed powder. With proper control of process variables, spherical particles are obtained that may be coated with agents to aid suspension and promote stability. However, the process is not normally considered for the preparation of ultrafine powders.

PHYSICAL ASPECTS

Stability of Suspensions

The chemical stability of a drug in suspension is controlled by the fact that the rate of degradation is related to the concentration of the drug in aqueous solution rather than to the total concentration of the drug in the product. Generally, a suspended drug decomposes only in solution as the solid phase gradually dissolves; that is, a solution concentration equal to the solubility of the drug is maintained. Drug degradation in a suspension usually follows zero-order kinetics, with the rate constant solely dependent on the saturation solubility of the drug in solution. Reducing the solubility of the suspended drug decreases the rate of degradation. The constancy of potency may be improved by selecting a pH value or range where the drug is least soluble or by replacing the drug with a less soluble derivative or salt. Decomposition in suspensions may also be described as a diffusion-controlled process or by catalysis initiated by environmental factors such as oxygen, light, and trace metals.

As a rule, the problem of suspension stability is complicated by the fact that pharmaceutical suspensions are affected at least as much by physical as by chemical factors.

Because a suspension exists in more than one state (liquid and solid), there are different ways in which the system can undergo chemical or physical change. Some of the more obvious difficulties involved in stability predictions are based on the fact that simple hydrostatic relationships (Stoke's law, etc.) used to define settling rates assume a spherical, deflocculated, free-falling particle that is not affected by particle–particle or particle–vehicle interactions. Suspensions that exhibit non-Newtonian flow are difficult to define in terms of the basic stability relationships. In addition, suspensions that are described in terms of a single representative particle do not reflect the influence of the entire particle size distribution.

Chemical stability predictions are sometimes complicated by the difficulty of determining the pH value of suspensions, which often changes because of surface coating of electrodes and differences between bulk-suspension and supernatant-vehicle readings. Accelerated elevated temperature stability testing often has a pronounced adverse effect on viscosity, particle solubility, and size distribution.

Deflocculated Suspensions

The empirical method of producing pharmaceutical suspensions is based on an attempt to prepare a stable deflocculated dispersion of a drug in a suitable suspension vehicle. In the past, a series of suspensions was often prepared using different concentrations of a favored suspending agent to identify the formulation that would produce the most homogeneous looking ("smooth") and stable suspension. The finished preparation was usually passed through a homogenizer or colloid mill to improve the final dispersion. Smooth looking viscous suspensions were produced; however, after some time, the drug particles settled slowly, forming a tightly packed sediment that was almost impossible to resuspend even with vigorous shaking. Primary particles or small aggregates, reaching the bottom of the container during sedimentation (settling), slipped past each other and produced compact layers of solids. The interparticle interaction in such compact sediments is relatively high because the interparticle distances are small, and the weak van der Waals forces of attraction, which decreases exponentially with distance, are appreciable. Such conditions frequently lead to the undesirable phenomenon of "caking or claying" and require extensive agitation for resuspension.

The physical instability of these early deflocculated suspensions led to other methods of producing physically stable pharmaceutical suspensions. For example, the density of the vehicle was made to equal or approach the crystal density of the suspended drug particles. If the drug particles are small enough and the vehicle sufficiently viscous, the particles remain suspended indefinitely in accordance with Stokes' law. Because the crystal density of most organic drug particles lies somewhere between 1.1 and 1.5 g/cm³, the only liquid vehicles for oral use with densities (at 25°C) high enough to be considered are Sorbitol Solution USP (1.29 g/cm³), Syrup USP (1.31 g/cm³), and high-fructose corn syrup (1.41 g/cm³). In practice, however, it is extremely difficult to prepare oral suspensions by the matched-density technique alone because dilution with water and other liquids reduces the vehicle density. Nevertheless, the use of high-density liquids as suspending vehicles often has a beneficial effect on physical stability.

The approximate settling velocities for nonflocculated particles of various average size were determined in the range of 0.2–200 μ m at density differences between solid particles and the suspending liquid of 0.2 and 2.0 g/cm³, respectively, with an absolute viscosity of the suspending liquid between 1 and 1000 centipoise (cP or mPa s). Terminal settling rates were calculated by a method described by Carpenter (6) for two concentrations of suspended solids, namely less than 2 and 20% vol. According to the analysis, permanent-type suspensions, which exhibit a settling viscosity of less than 0.14 cm per year at 25°C, can be obtained with a suspending liquid of a viscosity of ca 1000 cP, a density difference of 0.2 g/cm³ or less and an average particle size of the suspended solid of 0.2 μ m. This is a difficult set of criteria for most pharmaceutical suspensions to meet.

Because the distribution of particle sizes in most pharmaceutical suspension is generally above 1 μ m, deflocculated or peptized systems settle very slowly in stages, with the larger particles settling more rapidly than smaller ones. Ultimately, they form a tight, dense sediment that is difficult to resuspend. When viewed under a microscope, the dispersed suspension consists of individual particles, showing no apparent association.

Deflocculated suspensions are produced by three methods.

Mutual repulsion to large ζ -potential

This is best achieved by the adsorption of an electrolyte (KCl) or polyelectrolyte dispersant (sodium hexametaphosphate) on the surface of suspended particles to create a strong mutual repulsion between the microsize suspended particles. For example, moderate stability is

achieved when the ζ -potential is between ± 30 and ± 60 mV, and good to excellent physical stability is achieved when the ζ -potential is between ± 60 and ± 100 mV. As the size and density of the suspended particles increase beyond 1 μ m and 1.0 g/cm³, respectively, the effect of ζ -potential becomes less important.

Adsorption of a smaller hydrophilic or lyophilic colloid on larger suspended particles

When a strongly hydrated hydrophilic protective colloid, such as gelatin, is adsorbed on the surface of the suspended particles, the affinity for water exceeds the mutual attraction of adjacent particles for each other. The protective colloid and hydrogen-bonded water molecules form a protective hydration layer around each suspended particle.

Steric hindrance due to adsorption of an oriented nonionic surfactant or polyelectrolyte

Adsorption of a nonionic polymer (gum or cellulosic) or surfactant (polysorbate 80) of sufficient chain length creates steric hindrance and prevents adjacent suspended particles from coming close enough to join each other. Steric stabilization has the advantage over electrostatic stabilization in that it is relatively insensitive to the presence of electrolyte in the aqueous vehicle.

Because many pharmaceutical suspensions are not capable of reaching a state of complete electrostatic repulsion and producing and maintaining deflocculated particles, the technique has been regarded as unworkable by many investigators (1, 5).

Flocculated Suspensions

Matthews and Rhodes (8), Haines and Martin (7), Hiestand (5), and Ecanow and co-workers (9, 10) are credited with establishing the "structured particle" concept or flocculated pharmaceutical suspension. The following definitions should prove useful in avoiding confusion among three closely related terms: flocculation, agglomeration, and coagulation. The term aggregation can apply to all three.

Flocculation refers to the formation of a loose aggregation of discrete particles held together in a networklike structure by physical adsorption of macromolecules, bridging during chemical interaction (precipitation), or when the longer-range van der Waals forces of attraction exceed the shorter-range forces of repulsion. The floccule referred to as a "stable floc" usually contains varying amounts of entrapped liquid medium or vehicle within the networklike structure (Table 1).

Table 1 Suspension characteristics

Type	ζ -Potential	Relative settling rate	Sediment volume in vials at equilibrium	Drainage from vial	Resuspendability
Agglomerated or coagulated	0	Nonuniform	Low (lumpy)	Poor	Poor (may cake)
Overflocculated	0	Very high	Very high	Poor	Good
Slightly over flocculated	0	High	Moderate to high	Fair	Good
Slightly underflocculated	0	Moderate	Moderate	Good	Good
Underflocculated	0 to +10 mV	Slow	Moderate to low	Good	Fair
Deflocculated or peptized	+10 to +30 mV	Nonuniform	Low (stratified)	Good	Poor (cakes difficult to resuspend)

In agglomeration, a large number or mass of particles are closely bound together as aggregates in a dry (air) or liquid state. Coagulation or severe overfloculation refers to the massing of particles in a liquid state alone and sometimes in the form of a fluid gel structure. Aggregated particles of overflocculated systems, including adsorbed surface films, are in surface contact with each other, and each mass or coagula acts as a unit. The particles of such coagulated systems are held together by strong film-to-film bonds. Coagulated suspensions, like deflocculated suspensions, tend to “cake” on standing.

Soon after milling and suspension, unless steps are taken to prevent it, microsize particles tend to grow with time. Because the solubility rate of unprotected particles (Ostwald ripening) is higher than that of large crystals, crystal growth is favored until a more thermodynamically stable distribution of particles sizes is achieved. This phenomenon tends to promote “caking and cementing together” of particles.

The creation of a protective coat or boundary layer (with a hydrophilic colloid) about such particles offers the best protection to crystal growth. Because protective barriers may or may not flocculate, the substrate particles, the sign (positive or negative), and the charge potential on the particle surface (including a double layer) govern the choice between flocculation or dispersion (deflocculation).

The processes involved in the formation of suspensions are shown in Fig. 2. The flocculated state (C) may be reached either directly by wetting and dispersing hydrophobic particles (A) with a suitable flocculating surfactant, or indirectly by first wetting and dispersing to produce a dispersed or peptized particle (B) with a suitable surfactant and then flocculating with a suitable agent such as a hydrophilic colloid or polyelectrolyte.

In contrast to peptized or deflocculated particles, flocculated suspensions (C), which are considered pharmaceutically stable (although colloiddally unstable), can always be resuspended with gentle agitation. Severe overfloculation, on the other hand, caused by the addition of too much flocculating agent or by prolonged exposure to extreme thermal conditions (freeze–thaw cycles) tend to produce agglomerated or coagulated irreversible systems (E). The term plaque (platelike) is used to describe essentially flat agglomerates, whereas the term coagula (clumplike) is reserved for thicker, three-dimensional particle masses. In the absence of a protective colloid, the process of crystal growth is indicated by the arrow connecting (A) to (D). Some authors (11) refer to the “stable floc” as the partially flocculated state. Simply stated, the greater the number of particle-to-particle contact points in the cluster, the higher the degree of flocculation.

The main advantages of the stable floc are as follows.

The aggregates tend to break up easily under the application of moderate shear stress, such as gentle agitation of a bottle or vial, or by the flow through a small orifice (hypodermic needle and/or syringe) and reform an extended network of particles after the force is removed. Flocculation, therefore, imparts a structure to the suspension with virtually no increase in viscosity (Fig.3).

In contrast to peptized or deflocculated systems, the stable floc settles rapidly, usually to a high sediment volume, and may be easily resuspended even after standing for prolonged periods of storage time. The settling rate is not rapid and maintain content uniformity with reasonable periodic agitation. The stable floc can be produced by employing aseptic techniques, using vehicle components that are safe for intramuscular injection.

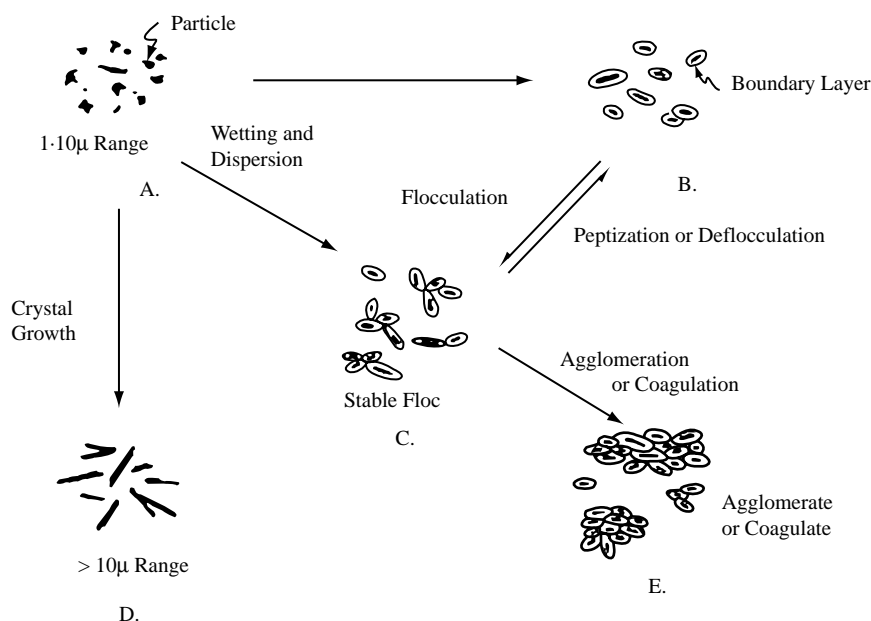

Fig. 2 Processes involved in the formation of suspensions.

Flocculated pharmaceutical suspensions are prepared using several methods. The choice depends on the properties of the drug and the class of suspension desired. The following examples illustrate how suspensions may be prepared by controlled flocculation procedures:

1. The wetting agent, polysorbate 80 (not more than 0.1–0.2% w/v of the final concentration), is dissolved in approximately half the final volume of aqueous vehicle. An anionic surfactant, such as Docusate Sodium USP, may be used as a wetting agent. This agent is, however, sensitive to pH and electrolyte concentration.

2. Ultrafine particles of the drug at the desired final concentration are uniformly and carefully spread over the surface of the vehicle, and the drug is permitted to be wetted undisturbed for as long as 16 h (overnight).
3. The wetted slurry is passed through a fine wire mesh screen (100 mesh size for ca 120 μm or larger) to remove poorly wetted powder. A single pass through a colloid mill can achieve the same result.
4. The slurry concentrate of the drug is agitated gently with an impeller-type mixer.
5. Small amounts of a 10% w/v solution of aluminum chloride hexahydrate are added dropwise, to the drug slurry from a buret or dropping pipette until the flocculation endpoint is reached (zero ζ-potential). To determine the endpoint, small samples are withdrawn and transferred to a graduated cylinder, an equal amount of vehicle is added to each, and the cylinders are gently shaken and permitted to stand undisturbed. The sample with the highest ratio of sediment to total suspension volume, exhibiting a clear supernate and good drainage characteristics is considered to be at the appropriate endpoint. Usually, no more than about 0.1–0.2% aluminum chloride hexahydrate is required to achieve the flocculation endpoint. A 10% solution of calcium chloride dihydrate may also be used as the flocculating agent. In this case, 1–2% of the calcium salt may be required for stable floc formation. If the drug fails to flocculate in the

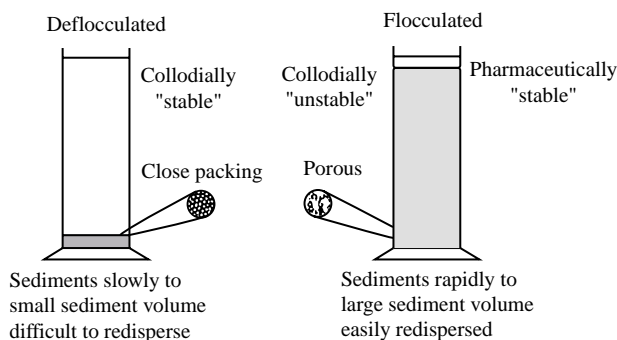

Fig. 3 Characteristics of flocculated and deflocculated suspensions. (From Ref. 5.)

presence of polyvalent aluminum or calcium ions, the water-insoluble drug particles are considered to be positively charged, and the procedure is repeated, this time using a polyvalent anionic flocculating agent such as 10% w/v sodium hexametaphosphate or 10% trisodium citrate.

6. After the flocculation endpoint has been established and verified, the other components (preservative, colorant, flavor, buffer, etc.) are added, dissolved in the liquid vehicle, and the slurry is brought to final volume with liquid vehicle.

Another popular method of preparing an oral suspension consists of suspending the drug in a solution of a hydrophilic colloid (gelatin or gum) or a diluted magma of bentonite, attapulgit, or colloidal magnesium aluminum silicate. The concentration of flocculating agent suspended in water, sorbitol, or syrup solution is between 0.1 and 1%. Overflocculation may be reversed by the careful addition of small amounts of a suitable surfactant or polyvalent deflocculating agent. Because clays cannot be used in injectable products, two other methods are described here.

One method, specially useful for preparing physically stable “noncaking” suspensions, consists of titrating concentrated aqueous solutions of soluble salt forms of acidic or basic drugs with a corresponding solution of a strong acid or a strong base. The water-insoluble free acid or base is precipitated at the pH of minimum solubility of the drug. The concentrations of the reacting solutions and the order of addition may be varied to produce an acceptable stable floc. If necessary, the electrolyte thus formed during precipitation may be reduced through slurry decantation or filtration to adjust tonicity and/or to maintain physical and chemical stability. This procedure can also be carried out under aseptic conditions.

A stable floc may also be produced by dispersing insoluble particles in a turbid or hazy vehicle consisting of finely dispersed or emulsified semipolar, liquid droplets, which cause the droplets to be adsorbed on the surface of the insoluble drug particles, resulting in a stable floc. Turbid aqueous vehicles have been prepared by the interaction of nonionic surfactants and preservatives. The concentration of surfactant and preservative required for haze formation may be reduced by the addition of small amounts of sorbitol to the vehicle.

Structured Vehicle

Another technique for the preparation of a stable suspension is based on the concept of the “structured

vehicle,” in which the viscosity of the preparation, under static conditions of very low shear, on storage approaches infinity. The vehicle is said to behave like a “false body” that is able to maintain the suspended particles in a state of more or less permanent suspension.

Structured vehicles are usually not considered for the preparation of parenteral suspensions because, owing to their high viscosity, such systems lack sufficient syringe ability for ease of use.

Bingham-Type Plastic Flow

Vehicles that exhibit the unusual property of Bingham-type plastic rheological flow are characterized by the need to overcome a finite yield stress before flow is initiated. Permanent suspension of most pharmaceutical systems requires yield-stress values of at least 2–5 Pa (20–50 dyn/cm²). Bingham plastic flow is rarely produced by pharmaceutical gums and hydrophilic colloids. *National Formulary* (NF) carbomers exhibit a sufficiently high yield value at low solution concentration and low viscosity to produce permanent suspensions. The carbomers, however, require a pH value between 6 and 8 for maximum suspension performance. The polymer is essentially incompatible with cationic resins, certain polyvalent ions, and high concentrations of electrolytes.

Thixotropic Flow

Thixotropy is a rheological property that results in yield stress on standing. Thixotropic flow is defined as a reversible, time-dependent, isothermal gel–sol transition. Thixotropic systems exhibit easy flow at relatively high shear rates. However, when the shear stress is removed, the system is slowly reformed into a structured vehicle. The usual property of thixotropy results from the breakdown and buildup of floccules under stress. A small amount of particle settling takes place until the system develops a sufficiently high yield value. The primary advantage of thixotropic flow is that it confers pourability under shear stress and viscosity and sufficiently high yield stress when the shear stress is removed at rest.

The concentrations of Bingham-type and thixotropic suspending agents required to achieve a yield stress of 10 Pa (100 dyn/cm²) is shown in Table 2.

Suspending agents such as a pseudoplastic (sodium carboxymethylcellulose) in combination with a clay (hydrated colloidal magnesium aluminum silicate)

or blends and coprecipitates of sodium carboxymethylcellulose and microcrystalline cellulose exhibit some thixotropic flow characteristics. Other pseudoplastics such as hydroxyethylcellulose or hydroxypropyl methyl cellulose may be required to overcome possible incompatibilities with sodium carboxymethylcellulose.

Emulsion Base

An emulsion base or a waxy-type self-emulsifier to develop structure or “false body” in suspension systems is widely used in both pharmaceutical and cosmetic systems. A dilute emulsion system is not often considered for suspension purposes because of the potential complexities involved in mixing emulsion and suspension systems. The drug particles are dispersed in the primary emulsion component prior to dilution with other vehicle components. Emulsifiers that exhibit Bingham plastic or thixotropic flow characteristics should have acceptable formulating properties (taste, stability, etc.).

FORMULATION OF SUSPENSIONS

During the preparation of physically stable pharmaceutical suspensions, a number of formulation components are used to keep the solid particles in a state of suspension (suspending agents), whereas other components are part of the liquid vehicle itself and have other functions in the dosage form.

- 1. *Components of the suspending system*
 - Wetting agents
 - Dispersants or deflocculating agents

Table 2 Concentration of suspending agents in water at 25°C required to achieve a yield value of 10 Pa

Agent	Concentration (%)
Carbomer 941	0.1
Carbomer934	0.2
Carrageenan	0.5
Carboxymethylcellulose	2.0
Xanthan gum	2.0
Algin	3.5
Magnesium aluminum silicate	5.0
Hydroxyethylcellulose	5.0
Guar gum	5.0
Tragacanth gum	5.0

Wetting Agents

Wetting agents are surfactants that lower the interfacial tension and contact angle between solid particles and the liquid vehicle. When the insoluble powder is added to a liquid vehicle containing a wetting agent, penetration of the liquid phase into the powder will be sufficiently rapid to permit air to escape from the particles. The resulting wetted particles either sink en masse or separate with low-shear agitation. The best range for wetting and spreading by nonionic surfactants is between a hydrophile–lipophile balance (HLB) value of 7 and 10, although surfactants with values higher than 10 are often used for this purpose. Common wetting agents and surfactants include: 1) anionic type (docusate sodium and sodium lauryl sulfate); and 2) nonionic type (polyoxyalkyl ethers, polyoxylakyl phenyl ethers, polyoxy hydrogenated castor oil, polyoxy sorbitan esters, and sorbitan esters).

Deflocculants and Dispersing Agents

Unlike surfactants, these agents do not appreciably lower surface and interfacial tension; thus, they have little tendency to create foam or wet particles. Most deflocculants, however, are not generally considered safe for internal use, and as a result the only acceptable dispersant for internal products is lecithin or a lecithin derivative (naturally occurring mixture of phosphatides and phospholipids). Because lecithins vary in water solubility and dispersibility characteristics, proper control of product specifications must be maintained to obtain reproducibility.

Flocculating Agents

Primary flocculating agents are simple neutral electrolytes in solution that are capable of reducing the ζ -potential of suspended charged particles to zero. Small concentrations (0.01–1%) of neutral electrolytes, such as sodium or potassium chloride, are often sufficient

to induce flocculation of weakly charged, water-insoluble, organic nonelectrolytes. In the case of highly charged, insoluble polymers and polyelectrolyte species, similar concentrations (0.01–1%) of water-soluble divalent or trivalent ions, such as calcium salts, alums, sulfates, citrates, and phosphates, may be required for floc formation, depending on particle charge (positive or negative). These salts are often used together as pH buffers and flocculating agents.

Thickeners, Protective Colloids, and Suspending Agents

Protective or hydrophilic colloids, such as gelatin, natural gums, and cellulosic derivatives, that are adsorbed on insoluble particles, increase the strength of the hydration layer formed around suspended particles through hydrogen bonding and molecular interaction. Because these agents do not reduce surface and interfacial tension, they function best in the presence of a wetting agent. Many of these agents are protective colloids in low concentration (<0.1%) and viscosity builders in higher concentrations (>0.1%). Suspending agents commonly used in pharmaceutical suspensions include:

- *Cellulosics*: sodium carboxymethylcellulose, microcrystalline cellulose (including coprecipitates and blends of the two), hydroxyethylcellulose, hydroxypropyl cellulose, hydroxypropyl methylcellulose, methylcellulose, starch, sodium starch glycolate, and powdered cellulose
- *Clays*: attapulgite, bentonite, magnesium aluminum silicate, kaolin, silicon dioxides
- *Gums*: acacia, agar, algin, carrageenan, guar, pectin, tragacanth, xanthan
- *Polymers*: carbomers, polyvinyl alcohol, povidone, polyethylene oxide
- *Sugars*: dextrin, maltitol, sucrose
- *Others*: aluminum monostearate, emulsifying waxes, gelatin

The other agents used in pharmaceutical suspensions (pH control agents, buffers, osmotic agents, stabilizers, vehicles, colorants, flavors, fragrances, and preservatives to control microbial growth) are not discussed in this article.

STERILE SUSPENSIONS

Sterile suspensions (injectable and ophthalmic) have characteristics that are not commonly shared by other

suspension systems, such as ease of resuspension, drainage, absence of foreign particulate matter and pyrogens, and syringeability in the case of injectable suspensions.

The preparation of a sterile suspension is a difficult manufacturing procedure. It requires strict attention to detail during the final recrystallization of the active drug substance, size reduction, and sterilization of the active drug substance and the suspending vehicle, aseptic wetting of the sterile drug powder with a portion of the sterile vehicle, aseptic dispersion and milling of the bulk sterile suspension, and aseptic filling of the finished suspension into sterile containers.

Various procedures for the manufacture of sterile suspensions have been reported by Akers et al. (12), Grimes (13), and Portnoff (14). At present, there is no pharmaceutically acceptable chemical agent that can be added to the finished suspension to make it both sterile and safe. Therefore, an elaborate program of sterility checks at critical phases of the operation is required.

An important property of a good parenteral suspension is syringeability; the ability of a parenteral solution or suspension to pass easily through a hypodermic needle, especially during the transfer of a product from vial to hypodermic syringe prior to injection. Increases in vehicle viscosity, vehicle density, and size and concentration of suspended particles make the transfer more difficult.

The most important of these features is probably viscosity. Fortunately, in the case of parenteral suspensions, viscosity is the easiest parameter to control. The preparation of a stable floc contributes little to the overall viscosity of the system (the so-called Einstein relationship) and does not adversely influence syringeability. Although the individual particles are held loosely together in large multiple aggregates, they are easily broken up and reformed during the passage from vial to syringe and syringe to injection site.

Drainage, or the ability of the suspension to break cleanly away from the inner walls of the primary container-closure system, is another important characteristics of a well-formulated parenteral suspension. Deflocculated to flocculated systems show this property, whereas overflocculated systems show some degree of poor drainage, also called "buttermilk appearance," a term that aptly describes this unsightly condition. Silicone coated containers, vials and plugs with dimethicone improve drainage and help reverse the tendency toward poor drainage by slightly overflocculated systems.

Resuspendability, or the ability to distribute settled particles with a minimum of shaking, is an important

characteristic of parenteral suspensions. Stable, flocculated parenteral suspensions that have been undisturbed for long periods of storage time are easily resuspended.

COSMETIC SUSPENSIONS

Cosmetic suspensions are available in two types. The first comprises pigmented products that are suspended in essentially aqueous vehicles (liquid makeup, eye-liners, mascara, and blusher). These products have a high solids content, high density, impalpable powders, and pigments permanently suspended in a primary oil-in-water emulsion-type base or a complex system of hydrophilic cellulose derivatives, clays, and/or polymeric film formers, in which the gelling and suspending properties of the vehicle often are reinforced by a small amount of a Bingham-type plastic such as carbomer.

The second type comprises pigment-containing nail enamels. The coloring tints, pigments, pearls, and lakes are suspended with the aid of an organophilic, thixotropic gellant, such as stearalkonium hectorite in a nonaqueous vehicle, containing butyl acetate, ethyl acetate, and isopropyl alcohol solvents in which the primary plasticized nitrocellulose and toluene sulfonamide—formaldehyde resin film formers are dissolved. Nail enamel is an excellent example of a permanent suspension in a nonaqueous vehicle.

TEST METHODS FOR PHARMACEUTICAL SUSPENSIONS

Tingstad (15) reviewed test methods for determining the physical stability of pharmaceutical suspensions. The procedures outlined are designed to determine the state of flocculation of a formulation. Because there is more than one method of preparing stable suspensions, the following test methods and performance criteria were found useful for determining the stability of both flocculated and dispersed systems.

Appearance

The appearance in a graduated glass cylinder or transparent glass container is noted. The following questions were addressed: At equilibrium, is the color and appearance of the sediment uniform? Are there breaks or air pockets in the sediment? Is the residual drainage

Fig. 4 Photomicrograph of a flocculated steroid suspension.

above the sediment uniform and minimal, or is there coagulated material adhering to the inside walls of the container?

Photomicroscopic Examination

The microscope can be used to estimate and detect changes in particle size distribution and crystal shape. Its usefulness can be enhanced by attaching a Polaroid-type camera to the microscope to permit rapid processing of photomicrographs (Fig. 4). These can be used, for example, to distinguish between flocculated and nonflocculated particles and to determine changes in the physical properties and stability. Sufficient fields and samples should be examined to make these determinations. Dilutions for microscopic examination should be made with supernatant external phase rather than with purified water. Individual particle size distributions can be accurately determined, using suitable electron instrumentation, for example, a Coulter Multisizer II (an electrical sensing zone instrument from Coulter Scientific Instruments, Hialeah, FL) or the Elzone 280 PC systems (Particle Data, Elmhurst, IL). General methods for particle size analysis are given in Fig. 5.

Color, Odor, and Taste

These characteristics are especially important in orally administered suspensions. Variation in color often indicates poor distribution and/or differences in particle size. Variations in taste, especially of active constituents, can often be attributed to changes in particle size, crystal

Fig. 5 General methods for particle size analysis.

habit, and subsequent particle dissolution. Changes in color, odor, and taste can also indicate chemical instability.

Sedimentation Rate, Sediment Volume, and Resuspendability

Simple, inexpensive, graduated cylinders (100–1000 mL) are useful for determining the physical stability of suspensions. They can be used to determine the settling rates of flocculated and nonflocculated suspensions and the sediment height at equilibrium. The falling height of the liquid–sediment interface of the suspension is determined as a function of time, and the sedimentation rate test is repeated periodically during storage. The sediment volume at equilibrium should be sufficiently large to support uniform resuspension with gentle agitation. The equilibrium sediment volume should be similar and reproducible batch after batch.

Volumetric graduated cylinders are used to determine the “*F*” or flocculation ratio, a value that represents the ratio of the sediment volume to the original suspension volume at a given time. It is used to measure the relative degree of flocculation and physical stability of suspensions. A sufficiently wide graduated cylinder should be used to overcome the “wall effect” which often influences the settling rate and equilibrium sediment volume of flocculated suspensions. Small graduated cylinders have a tendency to support suspensions because of the adhesive forces acting between the inner surface of the container and the suspended particles.

Viscosity

A Brookfield viscometer with a helipath attachment (Stoughton, MA) is a useful rheological instrument for measuring the settling behavior and structure of pharmaceutical suspensions and for characterizing the properties and stability of flocculated suspensions. The viscometer should be properly calibrated to measure the apparent viscosity of the suspension at equilibrium at a given temperature to establish suspension reproducibility. Apparent viscosity, like pH, is an exponential term, and therefore the log-apparent viscosity is an appropriate way of reporting the results.

Density

Specific gravity or density of the suspension is an important parameter. A decrease in density often indicates the presence of entrapped air within the structure of the suspension. Density measurements at a given temperature should be made using well-mixed, uniform suspensions; precision hydrometers facilitate such measurements.

pH Value

The pH value of aqueous suspensions should be taken at a given temperature and only after settling equilibrium has been reached, to minimize “pH drift” and electrode surface coating with suspended particles. Electrolyte should not be added to the external phase of the suspension to stabilize the pH, because neutral electrolytes disturb the physical stability of the suspension.

Freeze–Thaw Cycling

This is a useful guide to the physical stability of suspensions. If freeze–thaw cycling or elevated temperature exposures are chosen for physical stability testing, companion samples of a closely related marketed suspension should be included in the testing protocol for comparison purpose because pharmaceutical suspensions are not normally designed to withstand temperature extremes during storage (15–30°C optimum).

Drug Content Uniformity

This important testing procedure is best performed using either “unit of use” volume (e.g., 5 mL of oral liquid or a spray actuation of an oral inhalation product) or sampling from a well-mixed dispensing container from the top, middle, and bottom of the suspension.

Dissolution Testing

This technique (16) is still evolving. The favored approach at present is to submerge a small, known amount of suspension inside a secured Durapore (polyvinylidene fluoride) membrane pouch (Millipore Products, Bedford, MA) of suitable porosity in "teabag" fashion in a suitable dissolution medium using the USP Method 1 Paddle Apparatus (17). Optimization of experimental conditions (rate of agitation, volume and type of medium, temperature, etc.) must be established to achieve reproducible results.

Particle Size Measurement

Recently (18–20), with respect to the importance of particle size distribution in terms of particle characterization and product physical stability testing, there has been interest in newer light-scattering methods for particle detection called photon correlation spectroscopy (PCS). PCS methods can be applied to both micro- and nanosuspensions.

The information thus obtained from the use of such equipment includes mean particle size, particle size distribution, particle concentration, molecular weight estimation, polydispersity, particle shape, hydrodynamic interactions, and aggregation mechanisms.

In addition (21), there are several experimental options available for particle size measurement alone. They include single particle optical sensing (SPOS), laser diffraction (LD), and ultrasound attenuation (UA).

Other Procedures

Assays for potency, preservative effectiveness, compatibility with primary container-closure system, off-torque, simulated use testing, etc., should be handled in a manner similar to that used for conventional liquid solutions, with the provision that the container is well-mixed prior to sampling.

NANOSUSPENSIONS

Pharmaceutical nanosuspensions (22) are usually very finely dispersed solid drug particles in an aqueous vehicle for either oral and topical use or for parenteral and pulmonary administration. The key difference from conventional suspensions is that the particle size distribution of the solid particles in nanosuspensions is

usually less than 1 μm , with an average particle size range between 200 and 600 nm.

The techniques used for preparing nanoparticles are similar to those used to prepare more conventional drug particles and include controlled precipitation, ball milling using glass or zirconium oxide pearls, and high-pressure homogenization.

Nanosuspensions can be sterilized for parenteral use by using conventional steam sterilization in an autoclave, γ -irradiation, or membrane microfiltration in certain situations.

The key to long-term physical stability of aqueous nanosuspensions is the selection of a suitable water-soluble surfactant or polymer as an external particle stabilizer to prevent particle growth. Several potential stabilizers are lecithin, phospholipids, poloxamers, and polysorbates.

The physical stability of nanosuspensions may be monitored with the use of electron microscopic analysis.

The major advantage of pharmaceutical nanosuspensions is their ability to increase the in vivo absorption of highly-water-insoluble drugs by dramatically reduced particle size.

TABLET COMPRESSION: MACHINE THEORY, DESIGN, AND PROCESS TROUBLESHOOTING

Michael J. Bogda

Barr Laboratories, Inc., Pomona, New York, U.S.A.

INTRODUCTION

The most common method of drug delivery is the oral solid dosage form, of which tablets and capsules are predominant. The tablet is more widely accepted and used compared to capsules for a number of reasons, such as cost, tamper resistance, ease of handling and packaging, ease of identification, and manufacturing efficiency. Over the past several years, the issue of tamper resistance has resulted in the conversion of most over-the-counter drugs from capsules to predominantly all tablets.

Pharmaceutical products have been manufactured into compressed tablets for many years. During the 1950s, much research was devoted to the physics of compression (1, 2). Since that time, the pharmaceutical industry has attained a much greater understanding of the compression process, which resulted in the development of more robust pharmaceutical formulations (3–5). This has been achieved by the use of instrumented tablet presses and sophisticated data collection systems combined with the development of mathematical models.

During this time, a significant portion of the development work has been conducted on older equipment, which has been retrofitted to measure compression and ejection-force signals. Recent advances in the design of tablet compression equipment has resulted in higher-efficiency machines designed to optimize compression efficiency, minimize tablet weight variation, and provide greater flexibility, allowing the production of a greater range of products. However, the modern sophisticated machines still employ the same general concepts of operation: die fill, tablet compression, tablet ejection, and tablet scrape-off. Therefore, studies conducted on older equipment designed to evaluate the compression characteristics of materials, can offer significant insight into material behavior. However, modern machines provide greater accuracy and efficiency as follows:

- Improved material feed systems.
- Improved cam design and material of construction.
- Multistage compression.
- Isolated design for quick cleaning and changeover.

- Improved force-measurement techniques.
- Introduction of electronics to provide force control.
- Integration of on-line weight, thickness, and hardness test units providing weight feedback control to the force control unit, and
- High-speed single-tablet sorting to reject out-of-specification tablets.

Therefore, optimal product development can typically be performed on these machines that offer improved compression designs and material feed systems.

This article provides the basic information necessary to understand the general process of tablet formation. General machine design characteristics and tablet press nomenclature are presented. Tablet press control systems and process automation are discussed, followed by process and product troubleshooting on tablet compression equipment.

THE PROCESS OF TABLET FORMATION

The quality of a compressed tablet is determined by material fill characteristics and compression behavior. During compression, the rate at which tablets can be produced can be limited due to nonuniform material fill characteristics. Pending successful and reproducible material fill (die fill), the powder mass must form a coherent compact that stays intact upon ejection out of the die. Therefore, tablet press performance can be limited due to poor fill characteristics and/or poor compression behavior.

Die fill characteristics depend upon material flow properties that are primarily affected by particle size and shape. Additionally, high interparticle friction can have a detrimental effect on die fill characteristics due to powder bridging and nonuniform flow characteristics. A nonuniform particle size distribution may also lead to material segregation resulting in uniformity problems. Tablet presses employ volumetric filling of the material into the die cavity. Most high-speed tablet presses are equipped with force feeders, which use rotating paddles to promote

Fig. 1 The compression process.

uniform die fill characteristics. For certain materials, attention must be paid to ensure that the action of the power feeder does not cause overmixing or segregation of the material.

Upon proper die fill, one must consider whether the material will form a tablet. The tableting characteristics of powders depend on the viscoelastic properties of the material. The process of compaction has been defined as “the compression and consolidation of a two-phase system due to an applied load.” (6). The quality of the compact depends on the compression and consolidation of the powder mass, decompression of the compact, ejection from the die, and subsequent scrape-off from the lower punch. A schematic representation of the compression process is shown in Fig. 1. Because these viscoelastic properties are time dependent, both the magnitude and the rate of application (and release) of the compression force affect tablet quality.

Compression and Consolidation

During compression, the bulk volume of the material is reduced, resulting in the displacement of the gaseous phase (air) (6). Further increasing the force leads to particle deformation and rearrangement. At this point, the three principal modes of deformation are as follows:

1. *Elastic deformation*: A spontaneously reversible deformation of the compact in which, upon removal of the load, the powder mass reverts back to its original form. Most materials undergo elastic deformation to some extent. Compression of rubber would be by elastic deformation.

2. *Plastic deformation*: After exceeding the elastic limit of the material (yield point), the deformation may become plastic, that is, the particles undergo viscous flow. This is the predominant mechanism when the shear strength between the particles is less than the tensile or breaking strength. Plastic deformation is a time-dependent process.
3. *Brittle fracture*: Upon exceeding the elastic limit of the material (yield point), the particles undergo brittle fracture if the shear strength between the particles is greater than the tensile or breaking strength. Under these conditions, the larger particles are sheared and broken into smaller particles.

The compression process includes these three mechanisms. The individual characteristics of the material under investigation determine the extent to which each is active. Since some of these deformation characteristics are time-dependent, machine characteristics can have a major effect on tableting performance. These characteristics determine the rate of force application, dwell time (i.e., the time of maximum compression force, which depends on the punch head flat diameter and the tangential velocity), and the rate of decompression (see Fig. 1).

Typically for materials that undergo plastic deformation, as machine speed is increased there is less time for stress relaxation. Under these conditions, the tablets may cap and laminate. However, capping and lamination can be eliminated or minimized by slowing down the compression process (reducing the machine speed), lowering the rate of force application (larger compression roller diameter), or increasing the time of compression (multi-stage compression).

The final tablet properties are also affected by the consolidation (i.e., bonding) mechanisms of the powder which is influenced by its chemical nature, the surface area of the contact points, contamination (including film coatings such as magnesium stearate), and interparticle distance. The predominant consolidation mechanisms are listed below (7–10):

- *Mechanical theory*: As the particles undergo deformation, the particle boundaries intertwine to form mechanical bonds.
- *Intermolecular forces theory*: van der Waals forces bond the molecules together at the newly sheared surfaces of the particle boundaries. Microcrystalline cellulose is believed to undergo significant hydrogen bonding during tablet compression (11).
- *Liquid-surface film theory*: Thin liquid films form which bond the particles together at the particle surface. The energy of compression produces melting or solution at the particle interface followed by subsequent

solidification or crystallization thus resulting in the formation of bonded surfaces. Due to the applied pressure, the particles may melt or dissolve. As the pressure is released, solidification and crystallization occur.

The intermolecular forces theory and the liquid-surface film theory are believed to be the major bonding mechanisms in tablet compression. Many pharmaceutical formulations require a certain level of residual moisture to produce high quality tablets. The role of moisture in the tableting process is supported by the liquid-surface film theory.

During tablet formation, as load is applied to the powder mass, plastic deformation and brittle fracture create clean surfaces that are brought in intimate contact by the applied load. These surfaces bond together by a number of mechanisms such as those listed earlier. Plastic deformation is believed to create the greatest number of clean surfaces. Because it is time-dependent, higher rates of force application should lead to the formation of less new clean surfaces, resulting in weaker tablets. Additionally, because tablet formation is dependent upon the formation of clean new surfaces, high concentrations or overmixing of materials that form weak bonds result in weak tablets. Magnesium stearate, for example, forms weak bonds and easily wets surfaces. Therefore, over-lubrication or overmixing of magnesium stearate may lead to weak tablets.

Fragmentation (the creation of new clean surfaces) continues at the same time at which bonding and densification occur. A high quality tablet can be formed only when the process of bonding and densification exceeds fragmentation. The rates at which these functions occur are dependent upon the rate at which the forces are applied.

During compression, the powder compact typically undergoes a temperature increase (12, 13), which depends on frictional effects that are dependent, in turn, on the specific material characteristics, the lubrication efficiency, the magnitude and rate of application of the compression forces, and the machine speed. Typical temperature increases are between 4 and 30°C (14). As the tablet temperature rises, stress relaxation and plasticity increase, while the elasticity decreases and strong tablets are formed (15). Therefore, compression of material, at elevated temperature with increased ductility should result in stronger tablets.

It is believed that under certain conditions precompression is beneficial because it helps to remove entrapped air (16) and extends dwell time, thereby increasing the degree of stress relaxation and plastic deformation (17) as well as

the number of bonds, thus increasing tablet strength. Additionally, by extending the time of compression, precompression may provide a gradual loading and unloading of force. However, recent studies (18) suggest that a high level of precompression (higher than that of the main compression) may improve the tableting characteristics more than conventional tableting where main compression exceeds precompression. It is theorized that this effect is due to the high initial compression force that raises the tablet temperature, thereby increasing ductility and allowing greater plastic deformation. Application of the lower second compression force increases the formation of particle-particle bonds while minimizing particle-bond rupture, resulting in stronger tablets.

Decompression

After the compression and consolidation of the powder in the die, the formed compact must be capable of withstanding the stresses encountered during decompression and tablet ejection (19). The rate at which the force is removed (dependent on the compression roller diameter and the machine speed) can have a significant effect on tablet quality. The same deformation characteristics that come into play during compression play a role during decompression.

After application of the maximum compression force, the tablet undergoes elastic recovery. While the tablet is constrained in the die, elastic recovery occurs only in the axial direction. If the rate and degree of elastic recovery are high, the tablet may cap or laminate in the die due to rapid expansion in the radial direction only. If the tablet undergoes brittle fracture during decompression, the compact may form failure plains due to the fracturing of the surfaces. Tablets that do not cap or laminate are able to relieve the developed stresses by plastic deformation. Since plastic deformation is time-dependent, stress relaxation is also time-dependent. Therefore, tablet fracture is affected by rates of decompression (machine speed) since the compact may not have sufficient time to relieve the internal stresses created during decompression. Formulations which contain significant concentrations of microcrystalline cellulose typically form good compacts due to its plastic deformation properties. However, if the machine speed and the rate of tablet compression are significantly increased, these formulations exhibit capping and lamination tendencies.

The rate of decompression can also have an effect on the ability of the compacts to consolidate (form bonds). Based on the liquid-surface film theory, the rate of crystallization or solidification should have an effect on the strength of the

bonded surfaces. The rate of crystallization is affected by the pressure (and the rate at which the pressure is removed). High decompression rates should result in high rates of crystallization. Typically, slower crystallization rates result in stronger crystals. Therefore, if bonding occurs by these mechanisms, lower machine speeds (lower rates of decompression and crystallization) should result in stronger tablets.

Ejection

After decompression, the tablet remains in the die until it is ejected. During this time, a residual die wall force is exerted by the tablet on the die wall. Tablet ejection is defined by three stages (6):

1. The initial ejection peak force required to break the tablet adhesion to the die wall. This force is the highest force encountered during ejection and occurs over a very short period of time.
2. The force required to push the tablet up the die wall, which is typically lower than the ejection peak force. However, inadequate lubrication or damaged dies may result in slip-stick behavior where the tablet continues to adhere and break adhesions to the die wall surface. These conditions typically result in tablet failure.
3. Declining forces as the tablet emerges from the die.

Inadequate lubrication typically results in high ejection forces and possibly tablet failure. Ejection forces below 200 N are optimal, although forces up to 400 N are common. Ejection forces ranging between 400 and 800 N are considered high. Forces exceeding 800 N result in excessive heat build-up and could lead to machine damage and product failure. Inadequate lubrication can also result in striations along the tablet side wall, and picking and sticking.

Tablets that undergo significant elastic recovery upon decompression may exhibit capping upon ejection out of the die. Under these circumstances, the tablet builds up significant stress while in the die, which can only be relieved in the axial direction. As the tablet emerges from the die, its top portion can expand in both the radial and axial directions while the portion remaining in the die is confined. Shear stresses develop along the edge of the die and result in tablet failure.

Scrape-Off

Tablet scrape-off occurs immediately after ejection. Figure 2 illustrates a tablet stripper on a rotary tablet press. Typical forces during tablet scrape-off are 2 N or less. Scrape-off forces of 6 N or higher result in tablets

Fig. 2 Tablet stripper.

sticking to the lower punches and subsequently picking or, under extreme circumstances, shearing the bottom of the tablet. Frequently, shearing of the lower portions of the tablet due to scrape-off problems is mistaken for capping. However, this can be easily distinguished by examining the lower punches and rotating the press manually.

At high machine speeds, scrape-off problems may be encountered due to tablets backing up at the point of discharge. Under many circumstances, specially modified tablet strippers have proven to be beneficial for shaped tablets by discharging the tablets off the die table as quickly as possible (see Fig. 2).

Fig. 3 Rotary tablet press (top view).

ROTARY TABLET PRESS DESIGN

Pharmaceutical tablets are generally produced on rotary tablet presses (Fig. 3), where upper and lower punches reside in the upper and lower turret, respectively. The dies are inserted in the die table and secured by die lock screws. The upper and lower turret and the die table are precisely aligned. The movement of the punches is controlled by cam tracks and compression rollers. As the entire assembly rotates, the upper and lower punches move along the cam tracks to accomplish die fill, tablet compression, ejection, and scrape-off.

Tablet Compression

Tablet compression can be separated into the two distinct yet equally important phases of die fill-weight adjustment and tablet formation as shown in Fig. 4. As die fill begins, the lower punch face is initially flush with the die table surface as the lower punch enters the overfill cam at the entry of the feeder. The lower punch travels under the feeder and is pulled down by the overfill cam. At this point the lower punch has passed through approximately 50% of the feeder and the die cavity contains more material than required.

After overfilling the die cavity, the lower punch is adjusted to a constant height as it passes into the weight-regulation unit. The constant height, known as the fill depth, is measured as the distance between the lower punch face and the die table surface. Since die fill is volumetric, the constant height of the lower punch in the weight-regulation unit provides a constant volume of material. Therefore, the fill depth is affected by the density of the granulation. Variation of granulation density between batches results in different fill depths, whereas variable granulation density within a batch results in fluctuating fill depth requirements.

As the lower punch passes from the fill cam to the weight-regulation cam, the excess material is pushed back into the feeder and scraped off at the top of the die table by the excess material stripper and directed into a recirculation channel. On many modern presses, the lower punch is lowered by approximately 2–4 mm relative to the top of the die table after the excess material stripper. This lowers the material away from the top of the die table, minimizing uncontrolled loss as the upper punch enters into the die cavity after scrape-off. Under these circumstances the upper punch does not contact the top of the material until it enters into the die, minimizing material loss and weight variation. Additionally, lowering the slug of material away

Fig. 4 Rotary press (sequences of compression).

from the die table surface reduces material loss due to the centrifugal force of the rotating die table.

Overfilling of the die cavity is necessary to achieve uniform tablet weights and to optimize machine running conditions. However, at times excessive overfilling can lead to other problems such as excessive wear for abrasive raw materials, particle size reduction for friable granulations, material segregation, and overmixing of lubricant. Therefore, the effect of different machine running conditions must be evaluated for each different product separately.

The material that is directed into the recirculation channel is subsequently introduced back into the feeder at the tablet stripper or at the inside edge of the feeder. It is worth noting that the paddle in the feeder at the point of material entry rotates in the opposite direction as the turret to aid in die fill and induce flow back into the feeder.

Frequently the maximum machine speed may depend on die fill characteristics due to excess tablet weight variation at high machine speeds. However, because the compression characteristics of most pharmaceutical products exhibit viscoelastic properties, the press speed may also have a major effect on the compressibility of the material. For this reason, the ability to compress a tablet adequately is often the overriding factor to consider in tablet compression.

The process of tablet formation begins as the upper punch is lowered directly into the die cavity after the excess material stripper. As mentioned previously, it is advantageous if the slug of material is lower than the die table surface as the upper punch enters to minimize uncontrolled material loss and weight variation. After the upper punch enters into the die, the upper and lower punches begin to move toward each other as the punches ride along cam tracks toward the precompression rollers. At the precompression stage, the initial (and typically the lower) compression force is applied. Traditionally, tablet presses were equipped to apply a 20 kN maximum precompression force using relatively small compression rollers (approximately 100-mm (4-in.) diameter rollers). However, to improve flexibility, many modern rotary tablet presses are equipped with identical precompression and main compression force capabilities, allowing the application of 80–100 kN forces using 250–300-mm-diameter compression rollers.

After application of the precompression force, the punches move toward the main compression rollers where the final (main) force is applied. As the punches impact the rollers, the compression force increases until the punch head flat is tangent to the compression roller and maximum force is applied (see Fig. 1). The applied

compression force is a measured value and depends on the distance between the punches and the quantity of material in the die. After main compression, the upper punch is pulled out of the die cavity while the lower punch impacts the ejection cam to begin the ejection process. As the die table continues to rotate, the lower punch raises the tablet out of the die cavity to eject the tablet to the point of scrape-off.

Press Design and Layout

Modern rotary tablet presses are typically designed in separate machine sections (press zones). Typical sections to provide separation and isolation of the compression area from the other components are as follows:

- Upper cam section
- Compression section
- Lower cam section
- Lower mechanical section
- Electrical section

With the proper separation of these areas, only the compression zone is exposed to material, thus reducing cleaning and change-over time of the tablet press. In addition to the machine sections, an understanding of other machine subsystems is necessary, such as the lubrication system and the diagnostic systems (safety systems) to achieve optimal machine performance.

Modern rotary tablet presses are either single-sided or double-sided. A single-sided machine has one feeding station, one set of precompression and main compression rollers, and one discharge station. These machines produce one tablet per punch station per die table revolution. A double-sided machine has two feeding stations, two sets of precompression and main compression rollers, and two discharge stations, and produces two tablets per punch station per die table revolution. The double-sided machine operates identically to the single-sided machine with the exception that the excess material from the first feeding station passes into the second feeding station. A double-sided machine has a higher output than a single-sided machine. Its pitch circle diameter is also greater, which could result in weight uniformity and compressibility issues.

Bilayer tablet presses employ the same general design concepts as single-sided machines. Typically, a double-sided machine can be converted to a bilayer machine by replacing various cams. The material for each layer is introduced separately into each feeder and is removed from the die table to prevent contamination.

Upper cam section

The upper cam section is typically shrouded and sealed to prevent exposure of material. It consists of the upper cam track, all upper compression rollers, and all adjustments to the position of the upper compression rollers. The primary components of the upper cam section are as follows:

1. *Upper punch removal/dwell cams:* The upper punches are loaded and removed from the machine at this location. These cams typically reside directly above the material feeder. In many press designs, the upper punch dwell cam is designed to measure the tightness of the upper punches in the turret. A spring loaded cam designed to raise the upper punch slightly (1–4 mm) is connected to a proximity sensor. If the punches are too tight then the spring-loaded cam falls instead of raising the upper punches, thus tripping the proximity sensor and shutting down the machine. In alternative press designs, the upper punch tightness is measured in the upper-punch pull-up cam, typically by a strain gauge measurement of the lifting force.
2. *Upper punch lowering cam:* The upper punches are lowered into the die cavity by the upper-punch lowering cam. This cam is typically CAD optimized to minimize the acceleration and velocity of the upper punch as it enters into the die cavity. In this way, the upper punch travels in a smooth and controlled manner as it enters the die cavity, thus improving weight uniformity.
3. *Upper precompression and main compression rollers insertion depth adjustments:* Insertion depth for both precompression and main compression is adjusted in the upper cam section. The insertion depth determines the location of tablet formation in the die cavity relative to the top of the die table as shown in Fig. 5. It is measured as the distance at which the upper punch enters into the die at the tangent between the upper punch head and the compression roller. Insertion depth can be varied between 2 and 6 mm on most machines and is typically maintained between 3 and 4 mm. For precompression and main compression, the insertion depth should be maintained at approximately the same position. On most modern rotary tablet presses, the adjustments for precompression and main compression insertion depth are independent. However, on many older designs, the precompression roller is attached to the main compression roller assembly and its position is measured relative to the main compression roller position. In this way, the ratio of precompression to main compression remains constant as machine adjustments are made.
4. *Upper punch pull-up cam:* After compression, the upper punch enters into the upper-punch pull-up cam, which removes the upper punch from the die cavity. This cam

Fig. 5 Rotary tablet press layout.

provides an excellent location to measure the upper punch pull-up force that determines the tightness of the upper punches. Compared to the upper punch dwell cam, this location has the advantage of determining the punch tightness not only in the turret but also in the die cavity. Detection of tight punches at this location prevents almost all possibility of machine damage.

5. *Cam material of construction:* Both the upper and lower cam sections use cams to guide the punches while the turret rotates. These cams are typically made of various materials such as steel, bronze, or alloy. Most of the cam tracks in the turret are designed to smoothly guide the punches. Many modern rotary tablet presses use polymer composite cams for nonimpact points. These cams have excellent qualities in that they provide superior abrasion resistance and have self-lubricating properties minimizing cam and tool wear, heat generation, and noise, and ultimately resulting in increased machine speeds. However, cams that undergo impact (e.g., ejection cam) and stress (e.g., weight-regulation cam) require metal construction with good impact resistance. For this purpose, an aluminum-bronze alloy provides superior abrasion resistance and excellent impact strength.

Compression section

The compression section contains all components that are exposed to the material, such as the material hopper, the feeder, the excess material stripper, the upper and lower turrets, the die table, and the tablet stripper. Additionally, the dust-collection shrouds are located in the compression section. Proper shrouding of this area ensures that none of the upper and lower punch heads, compression rollers, and cam tracks are exposed to material. Proper maintenance and setup of the compression section is critical for optimal press performance. The primary components of the compression section are explained in the following section:

Material hopper: The material hopper is an integral part of the feeding system as shown in Fig. 6. Typically, it is capable of holding approximately 5–10 kg of material. Low level sensors are mounted in the hopper to signal an alarm, shut off the machine or activate a feeding mechanism to deliver more material when the product falls below this level. The material hopper should be symmetrical with steep discharge angles to promote mass flow and prevent funnel flow (rat holing) in the granulation. The discharge outlet of the hopper should be as large as possible reaching into the feeder to prevent material bridging.

On many machines the base of the hopper is equipped with a valve to shut off material flow to the feeder if necessary. Depending on the nature of the granulation, the hopper valve can contribute to material bridging. For materials with very poor flow characteristics, a slide valve may be preferable to a butterfly valve.

Older generation machines typically employ large hoppers, but more recent designs offer options to install

only a straight chute in place of a large overhead hopper. This design minimizes poor flow behavior and segregation due to funnel flow.

Gravity feed frame: Older machines typically employ gravity feed frames which rely on gravitational and turret rotational forces to achieve die fill. These feed frames provide good performance for materials with good flow properties but are typically limited to slow machine speeds. On the other hand, gravity feeders do not agitate the product and impart no energy. Therefore, they offer advantages for products where material segregation and overmixing are of concern. For example, products that are sensitive to overblending of magnesium stearate (i.e., exhibit capping when overblended) may exhibit improved compressibility by using a gravity feeder as opposed to a force feeder.

Force feeder: Force feeders are typically multi-chamber and multipaddle feeders as shown in Fig. 6. These feeders are critical to allow optimal press performance at high machine speeds with minimal weight variation. For products with good flow properties, the feeder should move the material from the overhead hopper to the dies with minimal mixing. Most force feeders contain two or three chambers and paddles. The three chamber/paddle system typically performs better than the two chamber/paddle designs. The top paddle and feed chamber are connected directly to the hopper and move the material from the overhead hopper to the filling chambers located directly above the die cavities. The top chamber eliminates the effect of the head pressure on material flow, thus providing uniform die fill regardless of the quantity of material in the hopper. Alternate systems offer level sensors that are designed to provide a constant quantity of material to the feeding chambers, thus also eliminating the effect of head pressure on material flow.

The force feeder chambers contain material baffles that function to prevent the material from randomly packing in the chambers, which results in nonuniform fill. Optimal systems provide minimal energy input and minimal particle mixing while providing uniform fill. The speed of the paddles can be synchronized with the die table speed minimizing tablet weight variation. The appropriate paddle speed can be determined by using a force-control system that displays the standard deviation of the compression force. The optimal feeder speed is determined by adjusting the feeder speed to achieve the lowest standard deviation in the compression force, which corresponds to the least weight variation.

A rectangular paddle design is typically used to minimize powder mixing in the feeder. However, for materials with poor flow characteristics (bridging in the hopper) due

Fig. 6 Material feeding system.

to interparticle friction, a round (or wedge) paddle design can improve flow by forcing interparticle slippage. Under these circumstances, round paddles provide a mixing effect with possible impact on uniformity, compressibility, and dissolution.

The feeder height above the die table surface is very important to minimize product loss and prevent scaling of low melting materials. The feeder height is usually maintained between 0.05 and 0.10 mm (0.002–0.004 in.). Very fine particles may require a feeder height of 0.025 mm (0.001 in.).

Excess-material stripper: The excess-material stripper is located immediately after the feeding system and scrapes off the excess material on the die table after weight adjustment. It is often overlooked during setup although it is one of the most critical components of the tablet press. A brass stripper is employed, which sits flush on the die table under spring tension. The material is scraped off just before the lowering cam. The brass stripper directs the excess material into the recirculation channel. A tail-over-die covers the die cavity after scrape-off to the point of upper punch entry. This design minimizes uncontrolled material loss due to flinging of material out of the die cavity at high rotational speeds.

Precompression and main compression rollers: After die fill and scrape-off, the punches rotate to the precompression station where an initial force is applied to the compact. The tablet is frequently partially formed during the precompression stage. Subsequently, the upper and lower punches move together under the main compression rollers where the final tablet is formed. The main compression roller is usually larger than the precompression roller. However, latest advances suggest that similar sizes for precompression and main compression rollers with the ability to apply similar loads may result in optimal tablet formation. The compression rollers are made of premium tool steels and are surface hardened.

Because the compression characteristics of powders are time-dependent (the exact extent of this dependency depends on the primary modes of deformation), the final tablet properties depend not only on maximum compression forces but also on the rate at which these forces (rate of deformation) are applied and removed. On a rotary tablet press, the rate of deformation is determined by the tangential velocity of the punch and the compression roller diameters. The tangential velocity of the punch is a product of the press speed and the die table circumference (i.e., die table rpm \times 3.14 \times pitch circle diameter). As the tangential velocity increases, the rates of compression and decompression increase while the overall compression time decreases. The roller diameter affects both the rate of compression and decompression. As the diameter

increases, the rates of compression and decompression decrease.

Optimal compression efficiency is achieved on machines that offer multistage compression with high precompression and main compression force flexibility (typically 100 kN maximum). The roller diameters should be as large as possible to provide the lowest possible rates of compression and decompression. If compression problems exist, the longest time for compression should be allowed by running at low press speeds and running on machines with a small pitch-circle diameter.

As mentioned previously, for certain types of products, precompression at a force level higher than that of main compression may increase tablet hardness. The author has found that for materials that primarily undergo brittle fracture, application of a precompression force higher than the main compression force can result in a higher tablet hardness. However, this is typically not the case for materials with elastic properties (e.g., products prone to capping and lamination) because these products require gradual application of force to minimize elastic recovery and allow stress relaxation.

Most heavy tonnage machines (80–100 kN capability for precompression and main compression) have no mechanical linkage between the upper and lower compression rollers. Therefore, for these machines, movement of the upper punch insertion depth does not result in an equal movement of the lower compression roller position. The compression rollers are typically mounted to a block assembly that is adjusted by an eccentric or a vertical slide adjustment (see Fig. 5). An eccentric adjustment typically results in a slight off-center alignment as the roller moves through all of its possible positions, whereas a vertical slide adjustment always maintains the roller along the center line. On older rotary tablet presses the rollers are attached to a rocker arm with one side fixed to the machine roof or base. On the upper compression roller, the other side of the rocker arm is mechanically linked to the lower roller rocker arm. In this way, adjustment to insertion depth results in simultaneous adjustment of both the upper and lower roller positions. As with the eccentric roller adjustment, rocker arm position adjustment results in a slight off-center alignment as the roller moves through all of its possible positions.

Although most rotary tablet presses operate by maintaining fixed roller positions during compression, some designs incorporate a compression compensator system in which the counterforce for compression is air pressure. This system compresses to a constant force and allows roller movement when the preset force is achieved. Under these conditions, potential exists to increase the time that the force is maintained near its peak value (approx-

mately 90% of maximum). Compression to a constant force should theoretically provide a more uniform tablet hardness and more uniform dissolution profiles while allowing a greater variation in tablet thickness.

Tablet stripper: The tablet stripper scrapes off the tablets from the lower punch and directs them down the discharge chute. On high-speed machines, special attention must be paid to the tablet takeoff to prevent tablet backup; modifications are necessary for shaped tablets, as shown in Fig. 2. On high-speed machines it is critical to move the tablets off the die table as quickly as possible. Under some circumstances, repositioning of the Plexiglas cover on the tablet stripper to provide minimal clearance between the tablet and the cover may prevent shingling of tablets. The height of the lower punch at the point of scrape-off should always be checked to verify that it is not below the die table surface. Typically the lower punch should protrude approximately 1–2 mm from the die table surface at the point of scrape-off. For deep concave tablets, a protrusion height above 2 mm may be necessary.

Tablet presses equipped with single-tablet rejection capabilities reject tablets at the point of scrape-off. Based on the compression force of the punch station, single tablets are sorted by using a compressed-air blow off or a mechanical fast gate. On single-sided machines (36 stations) both systems work well for both large and small tablets. However, double-sided, high-speed machines may present difficulties for large tablets at high press speeds.

Material recirculation: Material is recirculated from the center of the turret into the feed frame. Some press designs include recessed recirculation channels to minimize particle attrition and prevent excess material loss to the vacuum system. It is critical not to recirculate too much material because this can result in low product yields and can have a detrimental effect on the powder's physical properties, which could result in poor compressibility, uniformity, and final properties (e.g. reduced dissolution rate).

The point of re-entry of the granulation into the feeder corresponds to the location where the lower punch enters into the fill cam when it is flush with the die table surface. Therefore, the material from the recirculation channel is typically the material in contact with the lower punch face and is the first material to be filled for each die cavity. The effect of the material in the recirculation channel should always be evaluated when compression problems occur, which can be associated with the lower punch. An example would be a case where a granulation exhibits picking only on the lower punch and not routinely on all tablet presses. Additionally, this granulation is slightly underlubricated, very friable, and undergoes minimal brittle fracture.

Previous experiments showed that, as particle size decreases, ejection force and picking tendencies increase. It was determined that, for this product, excessive material recirculation resulted in a reduction in particle size and an increase in picking tendencies. However, the picking problem was seen only on the lower punches because the reduced particle size material came into direct contact only with the lower punches. The problem was minimized by reducing the amount of material in the recirculation channel and redirecting the material from the recirculation channel to incorporate it into the bulk of the material in the feeder, thus preventing it from contacting the lower punch directly.

Dust extraction: Adequate dust extraction is necessary to maintain high-speed operation for extended periods of time. The entire compression area should be shrouded to minimize dust infiltration into other press areas. Effective dust extraction minimizes dust and oil contamination on the surface of the tablets, which could produce black specs. Insufficient dust extraction results in excessive material build-up on the lower and upper punches leading to tight punches. However, the proper balance of dust extraction without high levels of material loss must be determined. If the dust extraction level is too high material could be extracted from the die cavities and the recirculation channel. Furthermore, the dust extraction systems preferentially removes the fine particles. Therefore, if the granulation is a direct-compression blend where the active constituent is of fine particle size, minimum dust extraction levels combined with minimal recirculation may be necessary to prevent a loss of active constituents (resulting in possible low assay).

Lower cam section

The lower cam section is completely sealed from the compression section. It houses the lower compression rollers, the entire lower cam track that guides the lower punches as the turret rotates, and all adjustments for the lower precompression and main compression roller positions. Additionally, any motors necessary for automatic machine adjustment are contained in this section.

Fill cam: The fill cam is designed to lower the punch to overfill the die cavity. Lower-punch fill cams are typically available in a variety of sizes that are changed depending on the final fill depth as determined by the weight regulation cam. Press manufacturers recommend a fill cam in which the weight regulation cam operates in the approximate center of the fill cam. Typical fill cams have a range of approximately 10 mm with an increment range of 4 mm (e.g., 0–10, 4–14, 8–18, and 12–22 mm). Special-order or very shallow fill cams are also available (e.g., 0–6 mm). Alternatively, some manufacturers offer a greater selection

of cams with a narrower range and lower increment (e.g., 5.5 mm range with an increment of 2 mm). These cams should offer greater precision in fill in certain cases. However, with the narrower range, minor changes in the granulation density could result in the necessity to change fill cams throughout the course of the run.

Flexibility in fill cam options offers advantages for specific problem areas. For example, if a material is very abrasive, a shallow fill cam should be chosen to minimize the amount of material that is removed from the feeder and subsequently returned to the feeder and the recirculation channel. A deep fill cam can cause overpacking of the feeder, which could result in jamming, temperature increases, and overmixing of granulation or lubricant.

Weight regulation cam: The lower punch travels from the fill cam to the weight regulation cam, which determines the final volume of material that remains in the die cavity after scrape-off. Proper design and operation of this unit is essential to ensure uniform tablet weights. In general, the unit should operate in a manner to ensure smooth punch travel minimizing punch chatter as the lower punch is raised to a precise and constant height.

The weight-regulation unit consists of several critical components that determine its efficiency of operation as shown in Fig. 7. The lower punch rides on the dosing rail that maintains the lower punch at a constant height at the final fill depth. In order to minimize vertical movement (and subsequently punch chatter) the head of the lower punch is held tight against the lower dosing rail by the holding-down cam which is spring loaded. To ensure that the holding-down cam is tight against the head of the lower punch, a 1–5 mm (0.04–0.20 in.) gap should be maintained between this cam and the lower dosing cam

when the lower punch rests on the dosing cam. During press setup, the fit can be easily checked by placing a lower punch in the weight regulation unit and verifying the absence of vertical movement of the punch. This function is critical to minimize tablet weight variation at high speeds. On many press designs, the weight regulation unit contains a safety cam on its inside.

The lower dosing rail and holding-down cam should always be made of a tough, abrasion-resistant material; aluminum–bronze alloy is highly recommended. The condition of the dosing rail and the holding-down cam should be checked every 6 months to ensure optimal performance. If significant wear is observed, the cams should be replaced or, in the case of the holding-down cam, reworked to provide a tight fit.

As the lower punch leaves the dosing unit, it is pulled down slightly (approximately 2 mm) by the lowering cam. Periodically the condition of the lowering cam should be checked to ensure proper lowering of the punch in order to minimize weight variation.

Many modern presses are equipped to measure the tightness of the lower punches. This function is critical to minimize machine damage as well as cam wear. As mentioned above, excessive cam wear increases tablet weight variation. Lower-punch tight sensors are typically mounted in either of the two locations. The transition cam from the fill cam to the weight regulation unit is an ideal location to measure lower punch tight forces because it is designed to raise the level of the lower punch to the final dosing height. In addition, the lowering cam can measure the counterforce to pulling down the lower punch.

Lower punch brakes: Most rotary tablet presses are equipped with lower-punch brakes that are Teflon tipped and spring loaded to apply constant pressure to the lower punches. Alternatively, some manufacturers apply pressure to a friction belt that provides resistance on the lower punches. The lower-punch brakes act as a “retention” system for holding the lower punches in place during press setup. More importantly, these systems help to minimize lower-punch chatter at high press speeds thus minimizing tablet weight variation. Some press manufacturers use the lower punch seals to retain the lower punches.

Precompression and main compression rails: The precompression rail provides the transition support for the lower punch from the weight regulation unit to the precompression roller, while the main compression rail provides the transition support from the precompression roller to the main compression roller. The optimal press designs provide positive support with these cams by ensuring that the lower punch head flat is always in contact with the rail surface. In this way, there is no abrupt vertical movement of the lower punch as it passes to the

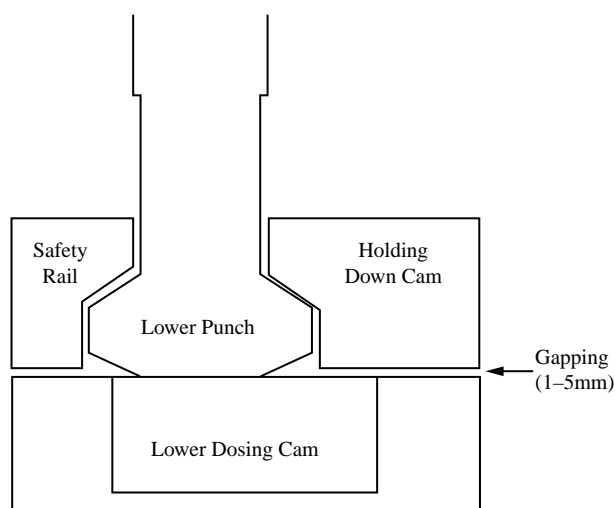

Fig. 7 Weight regulation unit.

compression rollers. Vertical movement of the lower punch before precompression and between the compression stations can cause the introduction of air into the bottom of the compact, resulting in capping at the lower-punch face. Many presses rely on the lower punch brakes or seals to prevent this type of movement. Under these conditions, vertical movement of the lower punches will gradually occur as these components wear causing periodic compression problems.

Adjustment of lower precompression and main compression roller thickness: The position of the lower compression rollers is adjusted from the lower cam section. As shown in Fig. 8, the position of the lower rollers relative to the upper rollers (i.e., insertion depth) determines the tablet edge thickness. Typically, the machine-control panel shows edge thickness on the indicator. However, adjustment of the edge thickness actually results in adjustment of the lower roller position only. For machines that have no mechanical link between the upper and lower compression rollers, the tablet edge thickness indication on the control panel is only valid at the specific insertion depth that was set during edge thickness calibration. However, for some of the electronic, fully automated machines, the machine automatically moves the lower compression roller during the insertion depth adjustment to maintain the same tablet edge thickness.

Ejection rail: After compression the lower punch impacts the ejection rail (or on some machines an ejection roller). Upon impact the tablet is broken free from the die

side wall and begins to move up the die as the machine rotates. The ejection rail should be made of a tough, abrasion resistant material such as aluminum bronze alloy.

Scrape-off rail: After riding up the ejection rail, the lower punch rides on the scrape-off rail to provide a constant height for tablet scrape-off. The height of the lower punch scrape-off can be adjusted to optimize the single tablet rejection height or the tablet scrape-off height.

Force overload system: Most tablet presses are equipped with force overload systems designed to prevent machine and punch damage. As stated previously, the compression force is not a set value, rather a measured value obtained from the fixed punch distance and the quantity of material in the die. On most tablet presses, a maximum allowable compression force can be set. This force setting is actually the counterforce to the measured compression force. If the compression force exceeds this counterforce, the compression assembly will back-off thus reducing the force. Most tablet presses use a hydraulic, air, or spring-loaded system on the lower compression assemblies (both precompression and main compression). In these systems the hydraulic or spring systems are calibrated to the measured force in the die and move instantaneously during an overload condition. Some of the more recent rotary tablet presses use strain gauges to measure the actual compression force for force overload (as opposed to force control). In these systems, the machine mechanically moves the compression assembly when the measured force is exceeded. Therefore, since these systems do not react as quickly as hydraulic, air, or spring systems they typically include a safety margin to initiate an overload condition prior to reaching the actual set value (e.g., 95% of maximum entered value).

Fig. 8 Force versus weight relationship.

Lower mechanical section

The lower mechanical section houses the main drive motor, the gearbox, the hydraulic pump, the lubrication pump, and the signal wire distribution. Proper venting and cooling of the lower mechanical section is essential to prevent machine damage and minimize heat generation. This section should be equipped with a cooling system for products that are sensitive to heat generation (e.g., contain low melting point components that are prone to picking and sticking).

Electrical section

The electrical section contains all electrical controls and components (e.g., programmable controllers, relays, contacts, and fuses), the signal wire distribution, and the

integrated or remote force control systems. On many machines the electrical section is connected to the front of the press, thus minimizing space requirements. However, modern fully automated machines use computers that may be sensitive to machine vibration, dust, and heat. Therefore, these electronics should be located remotely from the machine.

Lubrication system

Most high speed rotary tablet presses employ automatic lubrication systems during operation. Effective punch lubrication is essential for the movement of the punches in the turret, in the cam tracks, and under the compression rollers. Punch-lubrication systems allow high speed operation over extended periods of time while minimizing cam and tool wear and reducing heat generation.

The lubrication pump is typically maintained in the lower mechanical section and allows variation of both the lubrication interval and time duration. The quantity of oil delivered is normally determined by the oil distribution nozzles connected to the distribution manifolds. The upper punches are usually lubricated on the punch head flat via a felt pad located in the upper punch dwell cam or the upper punch lowering cam. On many modern designs the upper punch barrel is also lubricated. The punch barrel is lubricated via radially drilled holes in the turret that transports oil to the punches by rotational forces, or by overlubricating the punch neck and allowing gravity to transfer the oil down the barrel. Because the upper punch shaft has the greatest area of contact with the upper turret, lubrication of the punch shaft is critical to allow high-speed operation. Poor lubrication of this area can result in heat generation and metal expansion, ultimately causing machine seizure and severe damage.

The lower punches are lubricated at the punch neck. Oil distribution lines are frequently provided to lubricate both sides of the punch neck. Subsequently, gravitational forces distribute the oil over the head of the punch. The lower punch barrel is typically lubricated by radially drilled holes in the turret.

All presses equipped with punch-lubrication systems require oil and dust seals to prevent oil contamination in the product and dust contamination in the turret punch sockets. These seals are normally double lipped, designed to strip oil on one side and powder on the other. As mentioned previously, some press designs use the lower punch seals to retain the lower punches.

Inadequate punch lubrication can lead to excessive heat generation, which could affect tablet properties. An example is a granulation that primarily undergoes elastic and plastic deformation. This product was normally run on

a tablet press without an automatic lubrication system. Production requirements resulted in batch campaigning. At the beginning of the production campaign, the punches were lubricated and placed into the machine. Over the course of the first batch, the product was easily maintained within tablet hardness and thickness specifications. However, as the campaign transitioned into batches two and three, tablet hardness tended to increase while the thickness remained constant. Machine adjustments were made to maintain the hardness and thickness within specification, but in the end the hardness could not be maintained below the maximum limit without exceeding the thickness specification. At this point the machine was inspected and the lower punches were observed to be warm. They were removed, cleaned, lubricated, and placed back in the machine. Upon resuming production, the tablets returned to their original characteristics. In this case, the lack of a punch lubrication system combined with batch campaigning (extended running conditions) resulted in a temperature increase in the machine. For this elastic material, the increased temperature resulted in greater plasticity and more stress relaxation, improving the compressibility of the product. Although under many circumstances this effect would be beneficial, in the present case the improved compressibility resulted in out-of-specification product. The problem was resolved by removing the punches after each batch for cleaning and lubrication.

Instrumentation

Modern rotary production tablet presses are typically equipped to measure precompression and main compression forces. Additionally, measurement and monitoring of tablet ejection force can prove to be beneficial for specific problem products and for production troubleshooting. However, for most pharmaceutical products proper product development and optimization work eliminate the need to instrument a production machine for ejection force. Rotary tablet presses can also be equipped to measure both upper punch and lower punch pull-down forces. These measurements are primarily made to detect tight-running punches and are necessary on production machines only if the machine monitoring system uses direct force measurement for these functions. Tablet scrape-off force can also be measured, but this is only recommended on development machines. Scrape-off forces are typically below 6 N. Therefore, instrumentation of a tablet stripper requires highly sensitive instrumentation that is easily damaged.

Precompression and main compression forces are normally measured for the upper punches (20, 21). These forces are typically measured using strain gauges arranged in a full wheatstone bridge (22). Strain gauges are basically resistors applied to the metal surface in a specific orientation. Under load, the member deflects and the strain changes the resistance of the gauge. The change in resistance is proportional to the applied force. However, due to design differences, some machines measure the lower compression forces as opposed to upper compression forces. The compression force should be measured as close to the compression event as possible. For the most accurate and reproducible readings, the strain gauge should be in line with the compression event as opposed to off center at a remote location. This is easily accomplished on most rotary tablet presses by using a shear pin to support the compression rollers. However, the pin must not be rotated when the position of the compression rollers is changed. Therefore, this system is ideally suited for machines that change roller position by a vertical slide mechanism as opposed to an eccentric mechanism. Shear pins are typically custom manufactured, where quality depends not only on the pin design but also on the strain gauge receptivity and arrangement.

Many modern rotary tablet presses use off-the-shelf load cells for force measurement. These load cells are highly accurate, durable, and easily replaced and calibrated. However, the final accuracy and repeatability of force measurement in the machine not only depend on the quality of the load cell, but also on the design of the compression assembly and the placement of the load cell within the assembly.

Machines that utilize rocker arms with a mechanical linkage between the upper and lower compression assemblies are normally instrumented by applying a strain gauge to the upper rocker arm or to the mechanical linkage connecting the assemblies. The point of strain gauge application is "necked-down" to increase the sensitivity of the member. These instrumented members should be calibrated in the machine to account for the effect of other machine members on the measured force.

The force measurement system (strain gauges or load cells) should be calibrated on a yearly basis or after the compression assembly has been disassembled for any reason. The calibration should be made in the machine to assure accuracy. It is typically performed using a modified punch assembly and a calibrated load cell that are rotated under the compression roller to produce a load. The output of the machine force measurement system is compared to the output of the calibrated load cell. Many machine manufacturers use this single-point calibration to modify the strain gauge factor so that the two outputs are the same

at this load level. Subsequently, different load levels are tested and the error between the machine force measurement system and the calibrated load cell is determined. Alternatively, loads can be applied to the system ranging from the minimum to maximum compression forces. The outputs from the calibrated load cell and the machine force measurement system are recorded and a linear regression is performed on the data to calculate a new strain gauge factor across the entire force measurement range. Subsequently, different load levels are tested and the error between the readings is calculated.

PRESS CONTROL AND AUTOMATION

Conventional rotary tablet presses are controlled by periodically taking tablet samples from the discharge chute and checking their tablet weight, thickness, and hardness. If the tablet weight is outside of the established control limit, the operator increases or decreases the weight by adjusting the fill depth (increasing fill depth increases tablet weight and decreasing fill depth reduces tablet weight). If either the tablet hardness or thickness requires adjustment, the operator typically adjusts the tablet edge thickness on either main compression or precompression. Since there is normally an inverse relationship between the tablet hardness and thickness, the operator usually reduces edge thickness to increase tablet hardness (or decrease thickness) or increases edge thickness to decrease tablet hardness (or increase thickness).

Force and weight control systems use the same basic concepts as conventional machines. Force control systems monitor the tablet compression force and adjust the fill depth to maintain a constant force. Force control systems alone compensate for flow and density variations in the granulation, providing a constant fill quantity. Weight control systems, on the other hand, work in conjunction with the force control system as a secondary control loop and replace the manual function of the machine operator, periodically removing tablet samples to test tablet weight, thickness, and hardness. If the weight control system indicates that the tablet weight must be adjusted, the force control setpoint or the tablet edge thickness is altered resulting in a change in the fill depth from the force control system.

Force Control

During tablet compression, the distance between the rollers remains constant unless a machine adjustment is made to change tablet hardness or thickness. Additionally, all

Table 1 Tablet weight-control points and tolerance limits

Item	Description	Specification (mg)
UTL_{w_i}	Upper tolerance limit of individual tablet weight	105.0
$UTL_{\bar{w}}$	Upper tolerance limit of average tablet weight	103.0
$UCL_{\bar{w}}$	Upper control limit of average tablet weight	101.5
$Target_{\bar{w}}$	Target of average tablet weight	100.0
$LCL_{\bar{w}}$	Lower control limit of average tablet weight	98.5
$LTL_{\bar{w}}$	Lower tolerance limit of average tablet weight	97.0
LTL_{w_i}	Lower tolerance limit of individual tablet weight	95.0

tooling dimensions (tooling length and die cavity size) are constant within established standards. Under these conditions, for a specific material of uniform density, if the same volume of material is delivered to each die, the maximum measured compression force for each punch station is the same. If, on the other hand, different volumes of material are delivered to each die, the maximum measured compression force for each punch station is different. On this basis, adjustment of fill depth (fill volume) to maintain a constant compression force should result in a constant tablet weight. This concept is the general basis of all rotary tablet press force control systems.

The force control systems assume a linear relationship between tablet weight and compression force for a particular granulation, tooling set, and machine tablet edge thickness (i.e., distance between compression rollers). By establishing the relationship between compression force and tablet weight at a specific machine tablet edge thickness (as shown in Fig. 8), a force control system is able to maintain a constant tablet weight by maintaining a constant compression force. Additionally, a force control system is capable of monitoring every compression force and rejecting tablets when the forces exceed specific established limits (for both average forces and individual

forces), thereby essentially monitoring every tablet weight.

The first step in using a force control system is to establish the force versus weight relationship to allow calculation of the appropriate force control set points which correspond to the desired weight control points. Table 1 gives example of weight control points and tolerance limits for a theoretical product.

The tablet press is initially run at target conditions to make the product within specifications. For example, the tablets are made at target conditions of 100 mg at an average compression force of 10 kN. After establishing this point, the fill depth is adjusted to either increase or decrease the tablet weight and the corresponding compression force is measured. In the present example, the tablet weight was increased to 103 mg and the average measured compression force was approximately 13 kN. This procedure should be repeated for several different tablet weights. The data are used for regression analysis to calculate the required force set points that correspond to the weight control points as shown in Fig. 8 and Table 2.

As an alternative to performing regression analysis, fill depth can be adjusted to achieve each average weight

Table 2 Force setpoints

Item	Description	Specification (kN)
UTL_{F_i}	Upper tolerance limit for individual compression force	15.0
$UTL_{\bar{F}}$	Upper tolerance limit for average compression force	13.0
$UCL_{\bar{F}}$	Upper control limit for average compression force	11.5
$Target_{\bar{F}}$	Target for average compression force	10.0
$LCL_{\bar{F}}$	Lower control limit for average compression force	8.5
$LTL_{\bar{F}}$	Lower tolerance limit for average compression force	7.0
LTL_{F_i}	Lower tolerance limit for individual compression force	5.0

requirement and the resultant compression force can be recorded and set.

During normal production with the force control system in operation as specified above, the tablet press will operate to maintain the constant compression force of 10 kN by adjusting the fill depth (see Fig. 9). Most force control systems do not require the user to input the upper and lower force control limits for average compression force that are typically set by the manufacturer within tighter tolerances than those demanded by the weight requirements. The control system typically calculates the average compression force every revolution and compares it to the force set point. If the average measured compression force varies from the set point of 10 kN (outside of the tolerance set by the manufacturer) then the force control system adjusts the fill depth to return the force to 10 kN. If the compression force is outside the average tolerance limits (below 7 kN or above 13 kN), the machine will shut down and reject the tablets. This condition should correspond to average tablet weights outside of the 97.0–103.0 mg limits. Typically, the force control system is capable of adjusting the fill depth to maintain the compression force well within the tolerance limits. However, if the material has poor flow characteristics and exhibits bridging followed by surging, the system may be unable to compensate quickly enough to prevent these out of control conditions.

During the entire operation, if any of the individual measured compression forces goes outside of the individual tolerance limits of 5 kN or 15 kN (corresponding to individual tablet weights below 95 mg or above 105 mg), these individual tablets are rejected at the point of tablet scrape-off. Some machine designs are not effective at sorting individual tablets reliably and reject multiple tablets if this condition occurs. For most machine designs, the user can specify a maximum number of individual tablets that can be sorted per punch location or

per batch before the machine shuts down. Exceeding these maximum limits may indicate a problem punch or excessive weight variation for the batch, possibly related to a setup problem.

As described, a force control system maintaining a constant compression force will adequately compensate for variations in granulation density, thus providing more uniform tablet weights. However, operation of this system still requires an operator to periodically check tablet weight, thickness, and hardness. If during a weight check the operator determines that the average tablet weight has gone beyond the control limit, while the average compression force is still being maintained at its set point, the operator must take one of the following actions:

- The system is placed in manual mode (shut-off force control system) and the tablet weight adjusted back to target by increasing or decreasing the fill depth as necessary. Once the weight is within requirements, the force control set point is changed (and all other limits by the same amount) to the current value that is displayed and the machine is returned to the automatic mode.
- While in the automatic mode, the force control set point is increased or decreased to increase or decrease the tablet weight, respectively. For example, by increasing the force set point, the control system increases fill depth to achieve the higher compression force requirement thus increasing tablet weight. The machine is allowed to stabilize and tablet weight is checked. Adjustments are made until tablet weight is within specifications.
- While in the automatic mode, the machine tablet edge thickness is increased or decreased to increase or decrease the tablet weight, respectively. For example, by increasing the machine tablet edge thickness, the measured compression force is decreased. The force control system will then increase fill depth to return the compression force to its previous value thus increasing tablet weight.

Minor changes in the force to weight relationship over the course of a compression run are common. These may be due to changes in the compressibility of the granulation or to changes in the machine over the course of the run (such as temperature changes).

Tablet presses that use a compression compensator system, which in turn compress to constant compression forces and allow roller movement, operate by the same control theories as those presented for force control. However, these systems measure roller displacement as opposed to compression force and relate it to tablet weight.

Fig. 9 Force control system.

Fig. 10 Weight control system.

Weight Control

Weight control, as a secondary control loop to force control, allows automation of the tableting operation. The weight control system (Fig. 10) maintains the same limits as those presented for force control (Fig. 9). The machine assumes the place of the operator and periodically samples the tablet press to determine the tablet weight. The sampling requirements should be set to the same interval and number of tablets as those required for manual operation. Most weight feedback systems measure individual tablet weights and calculate the average weight for feed back purposes.

In the example given above, it is assumed that the weight feedback system will measure 10 individual tablet weights every 15 min. The force control system is in operation and is maintaining the average compression force at 10 kN. If during each 15 min. check, the average weight of 10 tablets is within the average control limits (see Fig. 10), no machine adjustments from the weight control system will be made. Alternatively, if the average tablet weight goes beyond the average control limits (above 101.5 mg or below 98.5 mg) the weight control system will initiate a change in one of the following ways depending on the machine:

Increase or decrease the force control setpoint to increase or decrease the tablet weight, respectively. The new force control set point is calculated by means of the machine manufacturer's control algorithm. Typically after adjustment to the new force control set point, the weight control system should resample and verify that the average tablet weight is now within the average control limits.

Increase or decrease the machine tablet edge thickness to increase or decrease the tablet weight, respectively. The new machine tablet edge thickness setting is calculated by the manufacturer's algorithm. After the new setting has

been made and the fill depth adjusted to maintain constant compression force, the weight control system should resample and verify that the average tablet weight is now within the average control limits.

The weight control systems that change the force control setpoint result in a change of the compression force throughout the run with a relatively constant tablet thickness. On the other hand, by changing the machine tablet edge thickness, the compression force remains relatively constant throughout the run while the tablet thickness varies. Since these adjustments are usually relatively small, both methods of machine adjustment typically produce similar results.

If during any check the average tablet weight exceeds the average tolerance limits (below 97 mg and above 103 mg) or an individual tablet exceeds the individual tolerance limits (below 95 mg and above 105 mg), the machine will shut off and reject the tablets. It is important to note that individual tablet weights exceeding the tolerance limits indicate that the tablet rejection system is not functioning properly.

Control and Monitoring of Weight/Thickness/Hardness

Tablet presses equipped to measure tablet weight, thickness, and hardness use the same concepts for force and weight control as presented here. These systems offer the additional flexibility of testing and controlling both tablet thickness and hardness. However, most machine manufacturers and tablet manufacturers have found that additional control of either tablet thickness or hardness is both difficult and costly. It is cost effective to only monitor tablet thickness or hardness and shut-off the machine if tolerance limits are exceeded. In this way, fully automated operation is possible without operator testing.

TROUBLESHOOTING

A proper understanding of a material's compression characteristics combined with a knowledge of tablet compression equipment allows efficient troubleshooting of production problems. Although there is no substitute for a robust granulation, a product can be optimized by examining all of the different machine factors that can affect performance. By applying a variety of the concepts discussed here, a large variety of processing problems can be eliminated.

Tablet Weight Variation

Excessive tablet weight variation can be caused by a variety of factors. For many granulations, the inherent poor flow characteristics of the material may be the rate limiting step, and simply slowing down the machine may reduce weight variation. Additionally, optimization of the feeder paddle speeds to minimize the standard deviation in the compression force should help to minimize weight variation. If weight variation is excessive, the following machine components should be examined:

- The tightness of the *hold-down cam* should be examined to verify that it is not excessively worn and is holding the lower punch tight against the dosing cam. If the previous product resulted in tight lower punches, premature wear may have occurred on this cam, causing increased weight variation.
- The condition of the *lower punch pull-down cam* should be examined to verify that it is not overly worn and that it drops the lower punch to pull the material in the die cavity below the die table surface.
- Both the condition and position of the *excess material stripper* should be examined to assure that it sits snug and level on the die table surface for complete scrape-off.
- Different types of *feeder paddles* can be used to promote flow (e.g., round feeder paddles are used for materials that exhibit bridging). The feeder speed should be optimized to minimize force and weight variation.
- The best *fill cam size* is that where the fill depth is centered in its range.
- A minimum amount of *material recirculation* is necessary to provide steady flow and fill. Too much recirculation can result in material back-up and reduction in the granulation particle size. The recirculation channel must be free of obstructions (i.e., broken tablets).
- If large tablets are being produced requiring deep fill depths, then *insertion depth* should be increased. Otherwise, as the punches pass from a deep fill to a shallow insertion depth, the uncompressed granulation will be pushed out of the die cavity resulting in material loss.

Product Yield

Product yield can be affected by a number of factors. Unfortunately, yield problems are not noticed until after the loss occurs. However, by paying attention to the following areas during setup, these problems can be minimized:

- Excessive material loss can be avoided by ensuring that the *excess material stripper* is flush against the die

table. Otherwise the material will be sucked into the dust extraction system.

- The *feed frame height* should be maintained between 0.05 and 0.10 mm (0.003–0.004 in.). For very fine particle size granulation, the clearance should be reduced to 0.025–0.05 mm (0.001–0.002 in.).
- The *fill cam size* should be reduced to minimize overfilling and material recirculation.
- Material in the *material recirculation* channel should be maintained at a minimal level. As more material is recirculated, the likelihood for loss is greater. The piece guiding the material from the recirculation channel to the feeder must be properly positioned.
- If the *insertion depth* is too shallow relative to the fill depth, material will be pushed out of the die and lost to the dust extraction system.
- Excessive *feeder speeds* cause excess material recirculation and increase material loss.
- It may be necessary to reduce *press speed*. As the press speed is increased, the turret rotational forces will sling more material to the outside of the turret from both the recirculation channel and the die cavity.

Low Hardness

Tablet hardness is affected by many factors. For troubleshooting purposes, it should be determined if the low hardness is due to capping or noncompressibility. For formulations that exhibit low hardness without capping, the following guidelines are helpful:

- For *multi-stage compression*, a machine should be equipped for both precompression and main compression with large diameter rollers.
- The *ratio of precompression to main compression* should be adjusted. For tablets that exhibit no capping problems, both precompression and main compression forces should be maximized.
- *Press speed* is reduced in order to increase total compression time.
- Formulations sensitive to lubricant levels may exhibit low hardness due to overmixing in the feeder. If the formulation contains a significant quantity of magnesium stearate or there is a shift in particle size thus extending the lubricant differently, overmixing can reduce tablet hardness. In this case, the *feeder speed* should be reduced to a minimum.

Capping and Lamination

Tablet capping and lamination typically create the most difficult problems, due to a variety of causes. Identification of the cause often leads to the solution. The basic concepts to alleviate these problems center on minimizing elastic

behavior while promoting plastic deformation. Depending on the exact nature of the problem, this can be achieved from a formulation perspective by modifying the formula to incorporate a plastically deforming matrix, by adding components to enhance bonding, or by increasing the moisture level. Alternatively, from a machine perspective the following guidelines should be followed:

- The *rate of force application* should be reduced by applying the compression force as gradually as possible. This can be accomplished by lowering the press speed or using a machine with a small pitch circle diameter.
- The *ratio of precompression to main compression* should be modified with gradual application of the precompression force followed by main compression. A precompression force that is too high can be harmful.
- The effect of reducing the *compression force* should be evaluated. In many circumstances, overcompression of a granulation will result in failure.
- A machine with large *compression-roller diameters* should be used to minimize the rate of force application.
- *Die cavity wear* must be investigated and the condition of the die cavities examined. If the dies are very worn, slip-stick behavior may occur during tablet ejection resulting in tablet failure.
- *Curled/damaged punches* promote tablet capping. Under these conditions the tools should be reworked or replaced.

Picking and Sticking

Tablet picking and sticking problems are typically related to formulation issues. However, in small scale manufacturing these problems do not occur frequently. Regardless, once a product is approved, it is difficult to make significant formulation changes. To minimize these problems the following areas should be considered:

- *Heat of compression*: Excessive heat generation during compression will increase the picking tendency of a low melting material. Use of cooling systems for the compression section or lower mechanical section may be helpful.
- *Press speed*: Lowering press speed and compression force reduces heat generation. Lower press speeds extend the contact time between the material and the punch face.
- *Precompression force*: Elimination of precompression may prevent picking. For example, some materials pick if the compression force is too low. Therefore, application of precompression at low forces may result in tablet picking.

- *Tool condition*: The condition of press tooling should always be evaluated when picking occurs. Polishing the punches and application of various coatings to the tools may help to eliminate picking for certain materials.
- *Start-up conditions*: Start-up should always be close to optimum conditions to prevent fouling the punch faces. If maintaining the force above a minimum is necessary to prevent picking, starting up near aim conditions of compression force prevents initial picking.
- *Tablet stripper*: The point of impact of the lower punches should be repositioned relative to the tablet stripper. Under many circumstances the stress of impact on the stripper can cause failure and sticking in logos.

Tablet Jams and Chipping

Tablet jams and chipping at the stripper reduce tablet quality and may contaminate the feeder resulting in weight variation. High speed machines typically have greater problems than slower machines. These problems are solved by focusing on the tablet stripper and lower punch ejection height.

- *Scrape-off height*: For many tablet types (e.g. deep concave tablets) the height of the lower punch at the point of scrape-off must be increased to ensure that the tablet is removed completely from the die when it impacts the tablet stripper.
- *Modified tablet stripper*: For shaped tablets, a modified tablet stripper that removes the tablets from the die table quickly prevents tablet back-up and breakage.
- *Height of plastic cover*: If the tablets exhibit layering or shingling, the height of the stripper cover should be lowered to just accommodate one tablet between the cover and the die table.
- *Tablet stripper*: The impact point of the stripper can cause chipping. Both the height and position of the tablet stripper must be checked. Damaged punches must be replaced or repaired.
- *Air assist*: If tablet jams cannot be eliminated by modifying the tablet stripper, an air assist blow-off at the tablet stripper may solve the problem.
- *Static eliminator*: In the production of lightweight tablets in a low humidity environment, static electricity may cause tablet back-up. In this case, installation of a static eliminator will improve tablet discharge.

SUMMARY

Optimal manufacturing of tablets requires good equipment and materials. The equipment is only a tool to achieve

the final goal of high quality tablets. However, if the materials have marginal flow and compressibility problems, machine flexibility allows the production of the highest quality product possible.

TABLET EVALUATION USING NEAR-INFRARED SPECTROSCOPY

Christopher T. Rhodes

Karen Morisseau

University of Rhode Island, Kingston, Rhode Island, U.S.A.

INTRODUCTION

Near-infrared spectroscopy (NIRS) continues to grow in importance as a useful analytical technique. It offers unique potential as a rapid, nondestructive method of quantitative and qualitative evaluation. NIRS has been used extensively in the food and agricultural industries for many years to determine moisture, protein, and starch content in grains (1). The pharmaceutical industry has been cautiously slow to accept NIRS as a commonly used technique, probably because of the absence of primary absorption bands. In recent years, an increasing amount of academic research is being carried out on the theory behind NIR. The use of NIRS for pharmaceutical applications has grown owing, in part, to technological advances in instrumentation and software.

Several reviews (2–7) have been published recently, attesting to its increasing popularity. Textbooks (8) relating to pharmaceutical uses of NIRS are becoming more common. Literature references pertaining to pharmaceutical uses date back to the early 1980s (9, 10). However, earlier NIR articles exist and were not taken seriously by the pharmaceutical industry at the time. In 1966, Sinsheimer and Keuhnelian (11) reported quantitative NIRS work with pharmaceutically active compounds pressed into pellets.

NIRS involves the multidisciplinary approaches of the analytical chemist, statistician, and computer programmer. The word chemometrics refers to the application of mathematical or statistical methods to measurements made on chemical systems of varying complexity. Chemometrics is defined (12) as the chemical discipline that uses mathematical, statistical, and other methods that apply formal logic to design or select optimal measurement procedures and experiments, and to provide maximum relevant chemical information by analyzing chemical data.

Chemometrics has found widespread use in the interpretation of analytical data and is relied on for the development of NIRS methods.

In pharmaceutical applications, NIRS is more often used as a secondary analytical technique than as a primary

tool. As a secondary method, a reference method is required to determine the reference component values that are to be used in the NIR calibration. The mathematical expression relating the component property (or properties) to absorbance is called a calibration model (also referred to as an algorithm). Using sophisticated spectral software, the analyst can correlate sample spectra to laboratory data, develop a calibration model, and apply that model to similar, new samples to predict constituent properties.

THEORY

The NIR region of the electromagnetic spectrum is from 800 to 2500 nm. The segment from 1100 to 2500, known as the Herschel region (13), is the range most often used in the analysis of pharmaceutical products. In the NIR region, the radiation can penetrate compacted materials such as tablets, providing a vast amount of spectral information about the sample.

The NIR region of the spectrum contains overtones and combination bands that are primarily attributed to hydrogen vibrations (OH, CH, NH). These overtones and combination bands are much weaker than the fundamental vibrations, thus, the molar absorptivities are much smaller than those of the corresponding infrared bands. Smaller molar absorptivities allow the use of undiluted samples and penetration of solid samples with good results.

There are several notable differences among the near-infrared region and other infrared regions of the electromagnetic spectrum. Conventional infrared instruments usually operate in the near-, mid-, or far-infrared regions, depending on the energy source and the detectors used. The wavelength range used for the NIR is just beyond the visible end of the spectrum and is referred to in terms of nanometers. Other regions of the spectrum are referred to in terms of wave numbers. Thus, the near-infrared region is $14,300\text{--}4000\text{ cm}^{-1}$, the midinfrared range is $4000\text{--}200\text{ cm}^{-1}$, and the far infrared is from $200\text{--}10\text{ cm}^{-1}$.

INSTRUMENTATION

NIRS instruments are typically designed as either transmittance or reflectance, with some allowing the user to switch from one to the other. The difference between the two instrument configurations lies in the positioning of the sample and the detector(s). In transmittance mode, the sample is placed between the monochromator and the detector so that the entire pathlength of the sample is integrated into the measurement. Transmittance measurements require higher frequency energy (800–1400 nm) because of the greater depth of penetration into the sample (14). In reflectance mode, the monochromatic light is illuminated directly onto the sample, and the reflected light is collected by detectors positioned at 45° angles to the sample.

Advances in instrumentation have resulted in a wide array of choices for analysts. These include instruments for specific applications with custom sample holders as well as general multiuse types. In the past 10 years, various patents have been issued for sample holders (15), sample supports (16), and a fiber optic system for dissolution (17).

An extensive product review of recent NIR technology was published by Noble (18). Enormous progress has been achieved in chemometrics and computing power, making many new applications possible. There are dozens of manufacturers of NIR spectrophotometers in the United States. There are many vendors of sampling components and software packages for data analysis. Research data of the most recent instrumentation and software are available directly on the World Wide Web, as most manufacturers maintain a Web site. There are numerous Internet (19) sites that provide links to professional spectroscopy societies, publishers of spectroscopy journals, and patents (20) related to pharmaceutical uses of NIR.

The US FDA's Division of Drug Analysis sponsored a cooperative study among manufacturers of NIRS instruments and pharmaceutical manufacturers to analyze a series of tablets, hard and soft gelatin capsules, and powders. One goal of the study was to demonstrate that a near-infrared scan was not unique among manufacturers. Another reason for the study was to establish FDA guidelines for the Instrument Qualification and Performance Verification of NIR instruments used in pharmaceutical analysis. Nine manufacturers participated in the study and represented makers of numerous types of monochromators (acousto-optical tunable filter or AOTF, dispersive and Fourier transform-NIR or FT-NIR). Ciurczak (21) reported a detailed account of the study to compare instrument performance in similar products, thus providing some comparative information to potential

buyers of NIR equipment. Ciurczak concluded that the quality of the spectra depends on the monochromator, and there is a range of noise variability in both FT-NIR and dispersive-type instruments. Examination of the spectra appearing in the report indicated differences in photometric noise and in spectral resolution (in certain regions) among instruments. One of the manufacturers, Analytical Spectral Devices, Inc., Boulder, CO, was identified in the study as the source of the donated spectra for the report and also provided their data over the Internet.

DATA ANALYSIS AND CALIBRATION

Obtaining Sample Spectra

The process of scanning a sample is quite simple and very rapid. The sample holder and surface must first be gently cleaned of debris and a reference (usually an internal ceramic Coor's standard) scan taken. The sample may then be placed in the sample holder, which may hold one or more of a specific type of sample. The sample is positioned, the lid closed, and the scan taken. Scan times are usually approximately 40 s. If multiple scans of the same sample are needed, the sample may be removed and rescanned. Instrument software facilitates the process and allows the spectra to be named and stored in data files.

Calibration

Calibration models are developed to determine the relationship between calibration set spectra and the constituent value of interest for those samples. Calibration involves taking spectra from many samples varying over the measurement range and also measuring the desired parameters. A rugged chemometric model for a complex sample may require hundreds to thousands of samples taken from all possible situations, in and out of specification, that it may encounter. Samples selected for calibration must contain all of the variables affecting the chemical and physical properties of the samples to be analyzed. To characterize each source of variation, it is recommended that 15 to 20 samples be run for each variable. Application of a math treatment, such as second derivative, prepares the raw spectral data for use in a regression and subsequent development of a calibration equation. This type of treatment results in a data file that will yield more information more easily than a raw data file.

Because NIR bands are mixtures of overtones and combinations, the intensity of the absorbance at particular wavelengths do not necessarily respond linearly to a change

in concentration. In the case of a mixture, band mixing may further disrupt any linear relationship between the intensity and the concentration. These are the reasons why the simple application of Beer's law $A = ebc$, where A = absorbance, e = absorptivity, b = path length, and c = concentration to NIR bands may not generate equations suitable for quantitation. Multiple regression techniques help avoid this problem. Linear calibration methods such as multiple linear regression (MLR), principal component analysis (PCA), and partial least-squares regression (PLS) are routinely used in NIR analyses. The choice of regression technique is subjective, depending on many factors. For further description of these techniques, see the introduction to multivariate calibration methods by Thomas (22). Other chemometric techniques useful in NIRS methods include BEAST bootstrap error-adjusted single-sample technique (BEAST), a nonparametric clustering algorithm used by Lodder and co-workers (23) to detect capsule tampering by NIRS. Qualitative NIR methods use pattern-recognition techniques to "train" the computer to identify an unknown material. Residual variance methods and discriminant analyses (Mahalanobis distance) were described by Mark and Tunnell (24), and were compared by Gemperline and Boyer (25). Gerhausser and Kovar (6) reported strategies for optimization of spectral libraries and compared two pattern-recognition methods to identify 117 drug substances.

Validation

Regardless of the mathematics used to interpret NIR spectra, the method must still undergo a validation process. The principal elements of ensuring linearity, accuracy, selectivity, and reproducibility of a quantitative method are required.

The validation process determines the amount of error owing to variation among the values in the population. It is used to check for the existence of a relationship between the calibration set and the validation set. Manufacturers of NIRS instrumentation include software packages that allow the operator to predict analytical results on data files that have been stored, thus allowing for validation of the calibration equation and testing for errors in the developed calibration. This enables calibration equation performance testing in terms of precision. The validity of these models depends on the ability of the calibration set to accurately represent the samples in the prediction set.

One source of prediction error is the inherent accuracy and precision of the reference analytical method used. If the reference method produces erroneous values that are consistently high or low, this bias will be reflected in

the prediction results. Other sources of prediction error relate to the reproducibility, stability, and repeatability of the NIR instrument. Reproducibility (precision) is validated by making repeated measurements of the same sample and removing it between runs. Small changes in conditions may occur owing to multiple insertions of a sample onto the instrument. Stability refers to similar changes that may occur over a longer period (hours or days). Repeatability refers to the instrument's ability to generate consistent measurements under the same conditions (without removing the sample from the instrument) over a relatively short period (seconds or minutes). All of these factors must be addressed to ensure the validity of the NIR calibration model.

Regulatory Issues

The American Society for Testing and Materials (ASTM) recently published an official document (27) providing a guide to spectroscopists for the multivariate calibration of infrared spectrometers. The scope of the publication, entitled *Standard Practices for Infrared Multivariate Quantitative Analysis* includes a description of multivariate calibration methods for the determination of physical or chemical characteristics of materials. This document is the first official standard for the application of chemometric multivariate analysis to near-infrared and infrared instruments.

Regulatory bodies around the world have given approval for NIR methods for a variety of purposes. In June 1995, the Medicines Control Agency (MCA) granted approval to Glaxo Wellcome in the United Kingdom for a NIR method for the identification and assay of Zovirax® (acyclovir) tablets. This is believed to be the first official approval for NIR granted by the MCA as an assay method for tablets.

In Norway, Wieders Farmasøytiske A/S received approval for the use of NIR as an alternative method for identification, assay, and determination of moisture content of paracetamol (acetaminophen) tablets. The Norwegian Medicines Control Authority approved the method in December 1996.

Other regulatory approvals are described in later sections of this chapter.

CURRENT METHODS OF TABLET EVALUATION

Official standards for the evaluation of tablets are given by the *U.S. Pharmacopeia* (USP) and other compendia and include uniformity of dosage units (weight variation,

content uniformity) and disintegration testing. Unofficial tests include those for mechanical strength (hardness, crushing strength) and resistance to abrasion (friability). A major disadvantage of current compendial methods of tablet evaluation is that they are time-consuming and destructive in nature. Once a test is performed on a sample, the integrity of that sample is usually lost (with the exception of weight testing) and no additional testing may be done on it. For example, a traditional quantitative analysis such as high-performance liquid chromatography (HPLC) typically calls for the tablet to be ground, followed by dissolution and dilution in a suitable medium. A significant amount of time and labor is required to run each sample in duplicate or triplicate. Other traditional methods of tablet evaluation also involve time-consuming sample preparation, such as KBr dilution for mid-infrared analysis.

The mechanical strength of a tablet plays an important role in the development and control procedures. Crushing strength is the most widely used test of mechanical strength. It is defined as the compression force that, when applied diametrically to a tablet, just fractures it (28). Tablet hardness depends on the weight of material and the space between the upper and lower punches at the moment of compression. Inconsistent hardness values are likely to result from variation in these parameters. The fundamentals of powder compression are given in a report by Leuenberger and Rohrer (29).

The Erweka hardness tester measures horizontal crushing strength by applying a load at 90° to the longest axis. This type of hardness tester is subject to two sources of inherent error: 1) the possibility of an incorrect zero, and 2) a scale that does not accurately indicate the true load applied. Other commercially used instruments include the Strong-Cobb, Monsanto, and Pfizer hardness testers. Variations in crushing strength values obtained from different types of hardness testers may be attributed to inaccuracies in instrument scale values, incorrect zero adjustment, and varying methods of applying the load. This necessitates calibration when comparing results from different types of testers. The physical dimensions and shape of the tablet may also contribute to the property of crushing strength.

The conventional methods of hardness testing for tablets also involve a subjective operator error. The scale on the Erweka hardness tester is divided into segments of 0.25-kg units. Very often, the sample under evaluation may produce a reading that falls between two divisions, and it is up to the operator to decide on the result.

Tablet-coating processes are commonly used in the pharmaceutical industry. Aqueous film coatings composed of cellulose derivatives and other polymers are useful for

the control of dissolution of drug from the tablet. Gravimetric analysis and HPLC are often used to determine the endpoint of the coating process.

ADVANTAGES OF NIRS TABLET EVALUATION

NIRS is a nondestructive method, thus, 100% inspection of batches is theoretically possible, allowing better control of product uniformity. NIR is also noninvasive, enabling subsequent evaluation of the same tablets by another method. Samples may be retained for further analysis by NIR or other methods, allowing a direct correlation between tests. Economic benefits are obvious for manufacturers, who may increase profits per batch because of the need for fewer retained samples. NIRS is particularly useful in the early stages of product development when the supply of the new drug is limited.

NIR analysis is rapid, requiring less than one minute to analyze a single sample. Also, NIR analyses do not require the use and ultimate disposal of organic solvents, thereby reducing environmental waste. Advances in instrumentation, fiber optics, and software offer many options. Portable NIRS units are not uncommon.

Accelerated degradation samples may be analyzed and returned to the associated storage condition at each of the appropriate time intervals, thus drastically reducing the number of samples taken from the batch.

Measurement of powders can take place directly through the unopened glass jar or vial because glass does not absorb in the NIR region. Direct measurement through the container further reduces sampling errors, which may be introduced when a sample is withdrawn.

Multiple components of a sample may be analyzed simultaneously. A single spectrum can be obtained and compared with several different calibration sets at the same time, allowing the measurement of several constituents at one time. This saves considerable time and labor.

LIMITATIONS OF NIRS TABLET EVALUATION

The initial calibration process for a substance or a product can be quite detailed. A calibration equation is needed for each constituent in the sample. NIR calibrations must be formulation-specific. The accuracy of the NIR method cannot be better than the reference method from which it was built. Ruggedness of the models improves when all expected types of variation are included in the model. Careful selection of representative

samples is imperative to the successful performance of the calibration. The choice of mathematical models depends highly on the character of the sample.

Another issue is that of transferability of the calibration model among instruments. This has been a significant obstacle to more widespread use of NIR methods. Transferability is especially important to multisite facilities, because it is needed to avoid time-consuming recalibration procedures. Calibration errors may occur among instruments because of slight differences in instrument response, especially if full-spectrum multivariate models are used. Shenk and Westerhaus (30) addressed the problem and proposed a standardization algorithm, which was modified by others (31, 32).

Physical attributes of the tablets can affect the calibration process. For example, scored tablets and those of differing geometries may produce more variable NIR spectra than flat, unscored tablets. Work in our laboratory (33) demonstrated a difference in NIR hardness testing of scored Avicel[®]-based chlorpheniramine tablets. Mixed calibration models composed of flat and concave tablets gave variable hardness prediction results, supporting the assertion that calibration models should contain samples of homogeneous composition.

Borer and coworkers (34) published a useful evaluation of sources of variability encountered in the NIR analysis of drug products. Analysts involved in NIRS method development should consider this report. Parameters included in the study included.

1. instrument settings (number of scans averaged per spectrum, iris opened or closed, frequency of reference spectrum collection);
2. data treatment (segment value used for second-derivative calculation); and
3. library design (total number of samples, number of days required to complete the library).

BULK DRUG PROPERTIES

Raw Material Identification

NIRS is useful for the analysis of both raw materials and finished dosage forms. Qualitative determination of pharmaceutical raw materials using NIRS was reported as early as 1982 (35). The largest variations in commercially produced excipients and actives appear to be in moisture content and particle size (36, 37). These parameters may be monitored by NIRS with relative ease. Incoming substances may be tested for immediate identity confirmation on the receiving dock by inserting a fiber

optic probe directly into the barrel. Spectral data for each lot of material purchased may be saved and added to the growing spectral reference library.

The use of NIRS as an identification method involves the establishment of a comprehensive library containing the spectra of many compounds. The sample is scanned and identified by finding the most similar item in the library. Comparison of the sample spectrum to the library reference spectrum is achieved by calculating (via computer) the cosine of the angle between the vectors of both spectra. This value is called the spectral match value (SMV) and may range from -1 to $+1$, with $+1$ being a perfect match. Plugge and Van Der Vlies (38) utilized the SMV for a NIR method of identification of ampicillin trihydrate. In their work, an SMV of 0.9980 was established as a minimum value for positive identity of ampicillin. The conformity index or CI is also calculated to establish the degree of conformity of a batch to specifications. Conformity testing detects deviations from normal processing by comparing the average batch spectra with the library of a representative collection of approved batches of the same material.

Particle Size

The measurement of particle size is a key issue in the formulation of many pharmaceutical products. Particle size distribution is known to directly influence physical properties of powders, such as dissolution rate, powder flow, bulk density, and compressibility. Conventional methods of particle size measurement include sieve analysis and laser diffractometry (39).

Ciurczak and associates (40) reported a NIR method of determination of particle size of pure, granular substances. The method is based on theories of reflected light, in which reflectance increases as the particle size decreases. The reference method was a low-angle laser light-scattering (LALS) particle sizer (Malvern). The researchers found linear results for particles above 85 μm , but less accurate results for smaller particles.

O'Neil et al. (41) described a NIRS method for measuring the median particle size of numerous compounds and excipients. Malvern data and NIR reflectance spectra of sieved fractions and bulk samples were used to construct multiple linear regression (MLR) and quadratic least-squares fit calibration models. The same group (42) reported success in measuring the cumulative percentage frequency particle size distribution of microcrystalline cellulose (Avicel) using NIRS. This study compared the use of three-wavelength MLR and principal component regression (PCR), each model using Malvern and NIR reflectance data. The PCR model

produced smaller SEPs, suggesting a more robust model than the MLR.

Frake and co-workers (43) extensively evaluated numerous chemometric techniques for the NIRS prediction of mass median particle size determination of lactose monohydrate. Models evaluated in zero order (untreated) and second derivative were MLR, PLS (partial least squares), and ANN (artificial neural network). The researchers concluded that there is more than one way to treat data and achieve a good calibration model. The group also confirms previous observations that derivitization of data does not remove "particle size effects" (previously thought to contribute to baseline shift).

Other researchers (44) have also reported NIR particle size studies.

Polymorphism and Racemization

Many drugs have the ability to form several distinct crystalline forms or polymorphs. Although the polymorphs are chemically identical, they are different arrangements of molecules and may exhibit different properties. Each polymorph may possess different energy levels and ultimately affect the dissolution rate of the compound. The infrared spectra of polymorphs may be expected to vary owing to different arrangement of functional groups (hydrogen bonding and polarization may be affected). Traditional methods for the identification of polymorphism are differential scanning calorimetry (DSC) and X-ray crystallography. However, these technique are destructive, and thus multiple runs of the same sample are not possible. Ciurczak (45) reported a NIR method of identification of the polymorphs of caffeine. Aldridge and co-workers (46) reported a NIR method of detection of polymorphism in which pattern-recognition methods were used to discriminate between the desired polymorphic form of a drug substance and another undesired polymorph. A significant outcome of this work was the successful transfer of the calibration between six other NIR instruments without the use of multivariate calibration transfer algorithms.

Gimet and Luong (47) used NIRS to determine whether the processing of a granulation resulted in racemization. Others (48) have also reported the differential identification of optically active forms.

Moisture Content

The classic methods of water determination are Karl Fischer (KF) titration, gas chromatography (GC), and loss on drying (LOD). Using near-infrared methods,

the presence of water is indicated by a major NIR absorption band at approximately 1920–1950 nm. The absorption maximum and peak shape depend on the degree of hydrogen bonding occurring within the environment where the water is located. The stronger the hydrogen bond, the longer the wavelength of the NIR absorption maxima. A second band attributed to water may appear at approximately 1450 nm and is attributed to bound water.

The NIRS determination of moisture content has been documented by numerous researchers (49–51). Plugge and Van Der Vlies (52) described a NIR method for ampicillin, which measures eight quality control criteria:

- identity,
- water content,
- crystallinity,
- ampicillin content.
- fraction of anhydrous ampicillin,
- residual reagent,
- residual organic solvents, and
- residual starting material.

DeThomas and VonBargen (53) patented a NIR fiber optic system for the measurement of moisture or "a constituent" in a powder. Berntsson, and associates (54) described a NIRS method to determine at-line moisture content in bulk hard gelatin capsules. Capsules were equilibrated at various humidities, and reference moisture content was determined by loss on drying.

Zhou and co-workers (55) at Eli Lilly and Company developed a NIRS method to determine moisture content in a freeze-dried drug product using gas chromatography (GC) as the reference method. A standard error of prediction (SEP) as low as 0.07% w/w was obtained using the NIR method in the range of 0.1–5.7% water. At very low water levels, the workers found the GC method to be more precise than the NIR method.

Corti and co-workers (56) developed a NIRS method to determine the water content of crushed ranitidine chlorhydrate tablets. KF titration was used as the reference method. Higher NIRS errors were found with the samples having a water content of less than 1%.

Dziki and coworkers (57) used NIRS to monitor the mobility of water within the sarafloxacin crystal lattice. The study involved the veterinary product sarafloxacin in an aqueous granulation process. A failed lot of the product was indistinguishable from an acceptable lot using X-ray powder diffraction, midinfrared spectroscopy, differential scanning calorimetry (DSC), and TGA. NIRS detected intermediate stages of water absorption in the granulation and enabled the process to be controlled.

An interesting report on NIR measurement of water in skin was published recently by Martin (58) at Helene

Curtis, Inc. NIRS measurements indicated four types of water contained in the skin. The workers presented tentative assignments for the absorption bands:

- lipid bilayers (1875 nm)
- secondary and primary water on protein groups (1909 and 1923 nm), and
- bulk water beneath the stratum corneum (1890 nm).

Studies were performed in vivo on two volunteers as well as in vitro using porcine skin. Although not directly related to tablet evaluation, the work is notable for its contribution to the transdermal delivery of drugs, potential NIR prediction of drug penetration through the skin, and conclusions regarding moisturizer use on the skin.

PRODUCT EVALUATION

Identification and Potency

Reports describing NIR methods of identification of solid and liquid dosage forms have increased in the literature during the 1990s (59–62). Earlier work has been reviewed elsewhere (see Introduction). Virtually all new NIR methods include product identification in the assay. Gottfries and co-workers (63) reported a NIR method for the measurement of metoprolol in controlled-release tablets. In their work, a comparison was made between the diffuse reflectance and transmission modes. The workers found better prediction of tablet strength using transmission mode and reasoned that reflectance spectra are more sensitive to the inhomogeneity of the material.

Ebube and coworkers (64) reported a NIR method that can distinguish between three Avicel® products owing to the varying particle sizes. The method was also designed to predict tablet hardness and lubricant concentration. Regardless of the small sample sizes used, good results were obtained.

North, Young and Leng et al. (65) recently presented an interesting comparison of NIR diffuse reflectance and transmittance for the analysis of tablets. Tablets used were of different drug content and size as well as coated and uncoated. Both methods produced excellent resolution of two tablet strengths. Uncoated and coated tablets produced different spectra by reflectance, but only a minimal difference was seen by transmission. Of two drug peaks seen in the reflectance spectra, only one band was observed in transmission because no transmission through the tablet occurred in the region of the second peak. Both methods produced difference in spectra as a result of difference in tablet size and surface curvature.

Merckle and Kovar (66) reported an assay of effervescent tablets (intact and powdered) by NIRS in transmittance and reflectance modes. Results of quantitative determination of acetylsalicylic acid (ASA) and ASA in combination with ascorbic acid and/or paracetamol were comparable in both transmittance and reflectance modes. Corti and associates (67) described a NIR transmittance analysis of coated tablets, using both whole and milled tablets.

Brashear and coworkers (68) developed a diffuse reflectance NIRS method to quantify lomefloxacin and polyethyleneglycol (PEG) within a polymeric implant. The properties of pore-forming excipients such as PEG are known to affect the rate of drug release from a matrix.

Sondermann and Kovar (69) described a study using NIRS for the identification of “ecstasy” street samples. Ecstasy tablets may contain either *N*-Methyl-3,4-Methylenedioxyamphetamine (MDMA) or *N*-Ethyl-3,4-Methylenedioxyamphetamine (MDE) as well as other amphetamine derivatives. In addition, various excipients were present, and nonstandardized production procedures contributed to inhomogeneous tablets. The authors researchers included a broad range of excipients in their calibration work and succeeded in constructing three PLS models for identification.

Identity testing of blister packaged tablets/supplies for clinical trials

A noninvasive NIR method was reported by Dempster and et al. (70) for the identification of tablets within blister packages. The method identified and discriminated various potencies of an experimental drug, placebo tablets, and clinical comparator tablets.

Aldridge and coworkers (71) described a NIRS method for nondestructive identification of blister-packaged tablets. The NIR method drastically reduced the assay time required by the previous TLC method. The TLC method required a full day to analyze 40 tablets, compared with the NIR method, which analyzed 10 tablets in 7 min.

Detection of adulteration

Lodder, Selby and Hieftje et al. (72) reported a NIR method of detection of capsule tampering. Several nonprescription products were selected for the study and tested with and without the addition of various adulterants. The NIR method provided a rapid, noninvasive way to screen products for known foreign substances. One limitation of the NIR method is the inability to predict which substances might be present in a product. Although the NIR spectra of many adulterants may be present in the spectral library, there is the possibility that a new,

unknown substance could be added to a product and not detected as an error in the NIR product spectrum.

Product development

In the drug-discovery field, chemists can use NIR to monitor the progress of reactions. Hearn and coworkers (73) reported a NIR method to monitor the preparation of compounds for screening as antituberculosis drugs. The reaction of isonicotinic acid hydrazide (INH) with carbonyl compounds in the preparation of Schiff bases was followed. Forbes and coworkers (74) described a NIR conformance test method to assay and identify two chemical intermediates used in the manufacture of Loracarbef, a carbacephalosporin.

Bauer, Dziki and Quick et al. (75) used NIRS to investigate the problem of dissolution failure in an erythromycin tablet formulation. The technique enabled the group to identify the presence of a dehydrated dihydrate produced during formulation. The dihydrate was found to gradually bind with magnesium hydroxide in the tablet formulation, thus delaying the process of dissolution. The use of NIR facilitated the development of a humidifying process that reversed the binding and increased the dissolution rate.

Quality Control Parameters

Tablet hardness

It has been shown (76, 77) that the NIR signal varies with a change in compression force. In other words, changes in tablet hardness result in an alteration in the NIR spectra of the sample. Presumably, increasing the compression force during the tableting process causes the tablet to be smoother as well as harder, thus causing less light scattering, leading to a greater absorbance and higher baseline. NIR hardness testing of tablets can be performed at the same time as other parameters such as identity, moisture content, and coating thickness.

Further work by Kirsch and Drennen (78) on NIR hardness testing has explored the use of various mathematical models for calibration. Other researchers have also reported NIR methods for the measurement of tablet hardness (64, 79).

Tablet coating

NIRS has been used to determine tablet-coating and core thickness. Kirsch and Drennen (80) evaluated the use of NIR at-line to monitor film coating in a Wurster column. The method was successful at predicting coating thickness of two coating formulations at various intervals during the process and was less time-consuming than wet chemical methods. Earlier work by Kirsch and Drennen (81)

described a NIR method to determine film-coating parameters of theophylline tablets. Increasing coating thickness, corresponded to increased NIR absorbance in certain regions of the spectrum. Calibration models were developed for tablet hardness, coating thickness and the prediction of time to 50% dissolution.

Buchanan and coworkers (82) at Merck reported a NIR method for evaluating a new coating-thickness manufacturing process. A precision film-coating process was tested whereby an immediate-release drug-active coating surrounded an extended-release active-drug core. The NIR method enabled the evaluation to proceed more quickly and less expensively than did the reference HPLC method. The implementation of the NIR method allowed rapid evaluation of tablets and assisted in identifying "dead zones" in the Wurster column, thus allowing immediate correction and revision of the process.

Determination of degradation products

Drennen and Lodder (83) reported a nondestructive NIRS method to monitor the decomposition of aspirin. In contrast to the multi step HPLC assay for salicylic acid and the USP identity tests for aspirin, the NIR method involved a 90-s scan of individual intact aspirin tablets. The workers correlated changes in spectra to the mass of water absorbed, the mass of salicylic acid formed, and the time the tablets spent in a hydrator.

Shimoyama and coworkers (84) reported a NIR analysis of photodegradation of poly(methyl methacrylate) using an in situ fiber optic device. This type of technology from a related discipline is notable as a potential application for pharmaceutical systems.

Characterization of powder blends and blend homogeneity

Powder blending is a fundamental step in the process of manufacturing pharmaceutical products. Only a homogeneous mixture can be properly subdivided to provide uniform doses of the active ingredients. The current procedures for monitoring blend uniformity require that the blending process be stopped at defined intervals to obtain samples of the blend. The samples are collected from different locations in the blending vessel using a sample thief. The samples are then sent to a laboratory and analyzed using traditional methods such as HPLC or UV until the active components are within specification for that formulation. This approach requires a significant amount of time and labor and may be subject to errors induced by sampling methods.

NIRS has been shown by several researchers to be useful for evaluating the powder-mixing process. Wargo

and Drennen (85) demonstrated the use of a NIR method to determine homogeneity of powder blends.

In 1995, the European Patent Office granted a patent to Dr. Paul K. Aldridge, Pfizer Central Research, Groton, CT, for an apparatus (86) for mixing and detecting on-line homogeneity. The apparatus involves the use of a diffuse-reflectance fiber optic probe interfaced on-line with a V-blender. Sekulic and co-workers (87) at Pfizer described the use of this apparatus for on-line monitoring of powder blend homogeneity. An 8-quart twin-shell V-blender was interfaced with a fiber optic probe at the axis of rotation. Spectra were collected at prescribed intervals, and data analysis was performed using a series of commercial software. Variability in the NIR spectra as a function of time was measured, and it was shown that this variability reached a minimum level sooner than what traditional blending times suggest. DeMaesschalck et al. (88) used the NIR on-line method described in article by the Sekulic and associates to design an approach for deciding when the blend is homogeneous. They calculated the average standard deviation between spectra taken at each time and used the dissimilarity between each new measurement and the ideal mixture spectrum to monitor changes in the mixture during the blending process.

Scientists at Merck were issued a U.S. patent in 1996 for a method (89) of measuring the homogeneity of tablets using NIR. It can be used to monitor the pharmaceutical material during the tableting process (powder mix, granular mix, and compressed tablets).

CONCLUSIONS

NIRS has proven to be a fast, reliable, and cost-saving method for numerous applications in the pharmaceutical industry. It is no longer the esoteric method it was once believed to be. The pharmaceutical industry has learned a great deal about NIRS from the agricultural and food industries. Concepts and techniques have been borrowed and fitted to the needs of pharmaceutical scientists. Users in all disciplines face common issue, such as calibration transfer, moisture contamination, particle size, and the rigors of calibrating multiple constituents.

NIRS possesses a great and, as yet, incompletely exploited potential in the area of identity testing of drug substances. It has already begun to replace traditional compendial methods of quality control. It has gained recognition from the FDA and other regulatory agencies, a signal to skeptics that NIRS is a solid alternative to traditional methods of analysis. Aggressive workers in the field are moving to develop and receive approval for NIR

methods that bypass the traditional reference methods. A greater understanding of the mathematics involved with NIR analyses has contributed to the wider use of NIR methods. Small companies that wish to use NIR analyses may find it wise to contract out their work to groups with more expertise because initial startup can be expensive and initial calibration work may be time-consuming.

We confidently predict that NIRS will rapidly become an established and standard method for many types of pharmaceutical analyses.

INTRODUCTION OBJECTIVES OF TABLET FORMULATION

The best new therapeutic entity in the world is of little value without an appropriate delivery system. Tableted drug delivery systems can range from relatively simple immediate-release formulations to complex extended- or modified-release dosage forms. The most important role of a drug delivery system is to get the drug “delivered” to the site of action in sufficient amount and at the appropriate rate; however, it must also meet a number of other essential criteria. These include physical and chemical stability, ability to be economically mass produced in a manner that assures the proper amount of drug in each and every dosage unit and in each batch produced, and, as far as possible, patient acceptability (for example, reasonable size and shape, taste, color, etc. to encourage patients to take the drug and thus comply with the prescribed dosing regimen).

The discovery of new therapeutic entities always initiates excitement, but the contributions of the formulation specialist are either not well understood or are often taken for granted and thus remain “unsung.” However, the drug and its delivery system cannot be separated. The general design criteria for tablets are given as follows

1. Optimal drug dissolution and, hence, availability from the dosage form for absorption consistent with intended use (i.e., immediate or extended release).
2. Accuracy and uniformity of drug content.
3. Stability, including the stability of the drug substance, the overall tablet formulation, disintegration, and the rate and extent of drug dissolution from the tablet for an extended period.
4. Patient acceptability. As much as possible, the finished product should have an attractive appearance, including color, size, taste, etc., as applicable, in order to maximize patient acceptability and encourage compliance with the prescribed dosing regimen.

5. Manufacturability. The formulation design should allow for the efficient, cost-effective, practical production of the required batches.

That tablets can be formulated to uniquely meet these criteria accounts for their emergence as the most prevalent oral solid dosage form. Although several different types of tablets may be distinguished, they are mostly made by compression, intended to be swallowed whole and designed for immediate release. This paper presents a systematic approach to the design and formulation of immediate-release compressed tablets.

MODERN TABLET FORMULATION DESIGN AND MANUFACTURE

Tablet dosage forms have to satisfy a unique design compromise. The desired properties of rapid or controlled disintegration and dissolution of the primary constituent particles must be balanced with the manufacturability and esthetics of a solid compact resistant to mechanical attrition.

Excipients are critical to the design of the delivery system and play a major role in determining its quality and performance (1). They may be selected to enhance stability (antioxidants, UV absorbers), optimize or modify drug release (disintegrants, hydrophilic polymers, wetting agents, biodegradable polymers), provide essential manufacturing technology functions (binders, glidants, lubricants), enhance patient acceptance (flavors), or aid in product identification (colorants). Thus a tablet formulation is not a random combination of ingredients, but rather a carefully thought out, rational formulation designed to satisfy the above criteria.

A long list of possible excipients is available to the formulation scientist, but certain external factors such as cost, functional reliability, availability, and international acceptance govern their selection. For example, although the official compendia provide standards for identity and purity of excipients, monographs may not provide tests to

assure their functionality. For instance, the NF monograph for Compressible Sugar provides no test for compressibility. The monograph for Lactose USP does not address the many particle size and tableting grades meeting monograph standards. The NF monograph for Pregelatinized Starch refers to grades that are “compressible and flowable in character,” but provides no specifications or tests for these properties. Nor do the monograph tests for disintegrants and lubricants necessarily relate to their functionality. The need to provide functionality tests or tests for properties clearly related to functionality may be as important as controlling identity and purity (2). This point has been made even more apparent in recent years with the emergence of multiple sources of such modern excipients as direct-compression filler-binders and the various classes of “super” disintegrants.

A major problem currently being faced by multinational firms and others who market in the international arena, is the lack of universal acceptability of excipients in different countries. The selection of excipients for international markets is often a compromise between functional efficacy, local restrictions, and cost and availability in the countries where the product is to be made. In recent years, the globalization of the pharmaceutical industry has brought about an intense interest in developing harmonized pharmacopeial excipient standards, Good Manufacturing Practices (GMP) for excipient manufacture, and safety evaluation guidelines for new excipients to eliminate or avoid trade barriers between different countries (3). The International Pharmaceuticals Excipients Council (IPEC), which consists of producers, users, and pharmaceutical scientists, was launched in 1991 to assist regulatory authorities in the United States, Japan, and Europe with harmonization. The separate organizations later formed in the United States (IPEC-Americas), Europe (IPEC-Europe), and Japan (JPEC) are now known as TriPEC and include, as of 1993, more than 100 excipient and pharmaceutical firms (3).

PREFORMULATION

The objective of preformulation studies is to develop a portfolio of information about the drug substance to serve as a set of parameters against which detailed formulation design can be carried out. Preformulation investigations are designed to identify those physicochemical properties of drug substances and excipients that may influence the formulation design, method of manufacture, and pharmacokinetic-biopharmaceutical properties of the resulting product.

Following is a generalized preformulation protocol appropriate for tablet dosage forms. For certain tests, it is assumed that the drug substance is multisourced (a previously new chemical entity whose patent has expired and which is available to the generic market) for which a USP monograph exists.

Identity and Purity

The study of any drug substance must start with the determination of identity and purity. Such tests are necessary to identify degradants and contaminants and may include organoleptic tests for color, odor, and taste. Purity tests can be found in the USP for almost all marketed compounds. Alternative methods can be employed only if they are validated against the USP procedure. Tests other than potency, which can help to identify or determine the purity of compounds, are melting point, specific rotation, pH, heavy metals, residue on ignition, etc. Impurities can occasionally affect stability, and metal contamination can catalyze chemical reactions. Impurities can also alter the color of drug substances. Techniques can be utilized to give a quantitative estimate of impurities such as the impurity index (II) and the homogeneity index (HI). An ordinary impurity test can be found in the USP that estimates impurities by thin-layer chromatography (TLC).

Crystal Properties and Polymorphism

Many drug substances appear in more than one polymorphic form. The form is determined by certain conditions during the crystallization step. Occasionally drug substances are precipitated in such a way that molecules do not organize themselves in any set pattern, resulting in an amorphous powder. It is also possible for solids to entrap solvents stoichiometrically to form solvates.

Even though they are chemically identical, the different polymorphic forms of a compound are associated with different free energies, and, therefore, have different physical properties that can impact significantly on product performance (4). These include differences in solubility and dissolution rate (affecting bioavailability), solid-state stability (affecting potency), deformation characteristics (affecting compactibility), and particle size and shape (affecting powder density and flow properties). The form with the lowest energy is more stable than the others. Although the other polymorphs are thus energetically unfavored, if kept dry, they may persist indefinitely and are called “metastable.” A metastable

form may be preferred, particularly for its ability to dissolve more rapidly.

Polymorphic transformation can take place during pharmaceutical processing, such as particle size reduction, wet granulation, drying, and even during the compaction process (5). Tests employed to determine crystal properties include differential thermal analysis (DTA), differential scanning calorimetry (DSC), and X-ray diffraction (4). See also the article Thermal Analysis of Drugs and Drug Products by D. Giron in this encyclopedia.

Particle Size, Shape, and Surface Area

Probably no characteristics of a drug substance are more important than particle characteristics in determining its performance in a formulation. This is particularly true in those cases where the drug is a poorly soluble nonelectrolyte or a free acid form with poor solubility at low pH values. Such drugs are likely to exhibit dissolution-rate-limited absorption, and if dissolution does not take place rapidly enough, a therapeutic concentration in the body fluids may never be achieved, the peak plasma concentration may be significantly delayed, or much of the drug may bypass that region of the gastrointestinal (GI) tract where absorption is best. Particle size reduction (e.g., micronization) is often utilized to enhance dissolution rate. Small particles present a larger surface area per unit weight to the dissolution media and hence dissolve more rapidly than large particles. Particle size and surface area are two of the most important properties determining the solubility rate of a drug and thus potentially its bioavailability. There are numerous examples of bioavailability problems and bioinequivalence due to the inappropriate particle size of the drug substance.

Particle size and shape also play an extremely important role in the homogeneity of powder blends and the unblending of powders in a mixer. Segregation in handling or during the compaction process has a significant effect on the content uniformity of the finished products. Particle size can also affect the stability of a drug substance in that it governs the surface area available for oxidation and hydrolysis. Surface area is critical for interaction with excipients in tablet dosage forms and can greatly affect stability. Methods to determine particle size and shape include light microscopy, scanning electron microscopy, sieve analysis, and various electronic sensing-zone particle counters. Methods available for surface area measurement include air permeability and various gas adsorption techniques.

Bulk Powder Properties

Bulk powder properties are extremely important in pharmaceutical processing (6). Knowledge of the true and bulk densities of the drug substance as well as of the excipients is extremely useful in

- Providing perspective as to the size of the final tablet and the size and type of processing equipment needed,
- Anticipating problems in the physical mixing of powders and the homogeneity of intermediate and final products because significant differences in true densities can result in segregation,
- Anticipating problems in flow properties, since that property is affected by density, and
- Identifying differences in different lots and raw materials from different suppliers because different polymorphic forms can be expected to exhibit different true densities.

A comparison of true particle density, apparent particle density, and bulk density can provide information on total porosity, interparticle porosity, and intraparticle porosity. Methods include true particle density measurements via helium pycnometry, mercury intrusion porosimetry, and poured and tapped bulk density.

The influence of sorbed moisture on chemical stability and the flow and compaction of powders and granulations is well established. The moisture content and hygroscopicity of excipients is particularly important as total product processing as well as finished product stability can be affected. Hygroscopicity, moisture-sorption isotherms, and equilibrium moisture content can be determined by thermogravimetric analysis and Karl Fisher titration methods.

The compactibility of relatively large-dose drug substances and formulations is another important property. Compactibility is of less concern for smaller-dose drugs for which direct compression fillers may be able to compensate for a lack of ability to form mechanically strong compacts. An instrumented tablet press (7) or compaction simulator (8) may be used to assess the relationship between the mechanical strength of the compact and the force (or pressure) employed to form the tablet. This relationship is the easiest of all compaction measurements to establish and provides important information on the ability of the material to form practical compacts. Measures of compact mechanical strength include hardness (or crushing force), tensile strength, and friability. Other more complex studies, more easily and perhaps best done using a compaction simulator, include measurement of the work or energy of compaction, pressure–density (Athy–Heckel) analysis, strain-rate sensitivity, and elastic recovery (9).

The Athy–Heckel analysis can provide information on deformation mechanism and give an estimate of the mean yield pressure of the material (10). A comparison of yield pressures determined at different punch speeds can give information on the strain-rate sensitivity of the material (11). If the major components of the formulation (including the drug) are strain-rate sensitive, the tablets produced on a high-speed production press may exhibit lamination or capping. Excessive elastic recovery may also indicate such tablet failure. The Hiestand indices (bonding and brittle fracture) may be used to assess the compactibility of materials under laboratory conditions (12).

For the evaluation of flow properties the following test methods may be used:

- Angle of repose
- Minimum orifice diameter,
- Carr index,
- Flow rate, and
- Direct observation of weight variation during tableting runs.

The ultimate goal of flow analysis is to identify the powder or powder blend that provides the least weight variation in the finished tablet. The more fluid the powder is, the more efficiently and reproducibly it should fill the die cavities of a tablet press. This more efficient and reproducible die fill should be reflected in increased tablet weights and reduced intertablet weight variation (13).

Solubility and Permeability

In many cases, the rate of dissolution in gastrointestinal fluids is the rate-limiting step in absorption. The bioequivalence requirements established by the FDA define low solubility as "... <5 mg/mL in water, and slow dissolution rate to be <50% in 30 minutes" (14). However, the solubility of a drug should be considered together with its dose; that is, even a very poorly soluble drug having a sufficiently small therapeutic dose may completely dissolve under physiological conditions. Thus, Amidon et al. (15) have defined a "high solubility" drug as one which at the highest human dose is soluble in 250 ml (or less) water throughout the physiological pH range (1–8) at 37°C. A "low solubility" drug is thus one which requires more than 250 ml of water to dissolve the largest human dose at any pH within the physiological range. The likelihood of having bioavailability problems requires both a consideration of the dose and a solubility volume of the drug and its permeability. Amidon et al. (15) created a Biopharmaceutics Drug Classification System (BCS) based on estimates of these two parameters:

1. Class I: High solubility and high permeability
2. Class II: Low solubility and high permeability
3. Class III: High solubility and low permeability
4. Class IV: Low solubility and low permeability

A jejunal permeability of at least $2-4 \times 10^{-4}$ cm/s, measured in humans by an intubation technique, is considered "high permeability." For many substances, this permeability corresponds to a fraction absorbed of 90% or better. The classification system provides a logical basis for estimating the risk of bioavailability problems. For example, Class I drugs (e.g., propranolol HCl, metoprolol tartrate) are expected to exhibit few bioavailability problems. On the other hand, Class II drugs (e.g., piroxicam) are more likely to exhibit dissolution-rate-limited absorption problems. Class III drugs (e.g., atenolol) are more likely to be prone to absorption (permeability) rate-limited absorption. Class IV drugs (low solubility–low permeability) present formidable obstacles to bioavailability. An in vitro–in vivo correlation (IVIVC) is expected only in the case of Class II drugs. An IVIVC could be expected for Class I drugs if the dissolution rate is slower than the gastric emptying rate. With a sufficiently rapidly dissolving Class I drug, little or no IVIVC is expected because gastric emptying (not dissolution) would be the rate limiting step. Little or no IVIVC is expected for Class III or Class IV drugs.

The FDA has adopted the BCS in developing a guidance that provides relaxed policies on scale-up and postapproval changes of immediate-release oral solid dosage forms (SUPAC-IR). For certain changes, requirements depend on the drug class, with the most liberal policies for Class I drugs, less liberal policies for Classes II and III drugs, and the least liberal policies for Class IV drugs. First issued as a draft on Nov. 29, 1994 for comment (16, 17), a revised version was published in the *Federal Register* on Nov. 30, 1995.

The intrinsic dissolution rate (IDR) of drugs is frequently measured in preformulation tests by the rotating disk method or Wood's apparatus (18). An automated IDR system, based on a modification of a standard dissolution apparatus, allows for attachment to the stirrer of a die in which the pure drug has been compressed with the tablet face flush with the bottom surface of the die (19). The IDR may be used to detect different polymorphs as well as to judge the risk of a drug exhibiting dissolution-rate-limited absorption. Kaplan (20) suggested that an IDR of higher than $1 \text{ mg cm}^{-2} \text{ min}^{-1}$ indicated that dissolution-related absorption problems were unlikely, whereas an IDR lower than $0.1 \text{ mg cm}^{-2} \text{ min}^{-1}$ indicated dissolution-rate-limited absorption.

Drug-Excipient Compatibility Studies

A knowledge of the interaction of drugs and excipients is essential in the initial formulation of a product. It may also be necessary later on during processing scale-up, when problems arise, to determine if incompatibilities exist which affect manufacturing or stability. Drug-excipient interactions are often directly related to the moisture present in one or another of the components or to the humidity to which the formulation is exposed during processing or storage. These studies are always carried out at accelerated temperature and humidity conditions, even though it must be recognized that some interactions are physical (melting and volatilization) and not chemical and that accelerated aging may not be predictive. Tests for excipient-drug interactions are usually conducted on blends of the pure drug and excipient in ratios similar to those in the final dosage form. For example, excipient-to-drug ratios are higher for filler-binders than for lubricants and disintegrating agents. These studies are often performed with the help of a factorial or fractional-factorial experimental design (21). Powders are physically mixed and may be granulated or compacted to accelerate any possible interaction. Samples can be exposed in open pans or sealed in bottles or vials to mimic product packaging. Evaluation of samples includes

1. Visual inspection for changes in color or texture.
2. Both HPLC and TLC are commonly employed with unstressed samples being used as controls. In general, only qualitative results are important initially.
3. Differential thermal analysis is applied and the appearance or disappearance of one or more peaks is noted. Isothermal microcalorimetry can also be employed as well as a thermal activity monitor (TAM) technique.

Compatibility studies are essential in characterizing both raw materials and finished formulations. It has been argued that binary drug-excipient screening studies are inefficient, unrealistic, and ignore processing variables. A better approach may be to carefully select potential excipients based on known chemistry and published compatibility data, and perform miniformulation stability studies (22).

Formulation Design

Based on the preformulation information, decisions can be made regarding formulation design and process strategy. Initial guidance may be provided by the proposed dose. Relatively low-dose drugs can often be tableted by direct compression, a term that is applied to the process by which tablets are compressed directly from blends of the active

ingredient and suitable excipients. No wet or dry granulation is required, although the drug may occasionally be sprayed out of solution onto one of the excipients to ensure uniform dispersion of drug in very low dosage. Larger doses of poorly compactible drugs may be granulated prior to tableting. The process steps required and the choice of excipients are often governed by other properties of the drug.

Analysis of Critical Variables and Formulation Development

Based on the analysis of the preformulation data, likely excipients are selected and small batches may be produced. The number and size of the batches depend on the availability of the drug substance. The batches are intended to assess the feasibility of the formulation, including the types and levels of excipients, as well as the process and its operational variables, such as order of addition, mixing times, compression force, granulation time, etc. The goal is to develop a formulation and process that meets the criteria set forth earlier under Objectives.

MANUFACTURE

Traditionally, tablets have been made by granulation, a process that imparts two primary requisites to formulations: compactibility and fluidity. Both wet granulation and dry granulation (slugging or roll compaction) are used (Table 1). Regardless of whether tablets are made by direct compression or granulation, the first steps, milling and mixing, are the same; the subsequent steps differ.

The wet massing of powders is typically carried out in high-shear mixers prior to wet screening. The wet granules are often dried in fluidized-bed equipment, enhancing the efficiency of the process. Alternatively, wet granulation may be carried out in fluid-bed drier-granulators in which the liquid phase is sprayed onto fluidized powders while the hot air flow dries the granules. This process reduces the number of handling steps and the time and space needed for granulation; it can be automated. The advantages and disadvantages of wet granulation are given in Table 2. See also Granulations by H.G. Kristensen and T. Schaeffer, Vol. 7 (1st Ed.), pp. 121–160, of this encyclopedia.

Regardless of the granulation method, the comparative simplicity of the direct compression process offers obvious advantages, such as

1. Economy
2. Elimination of heat and moisture

Table 1 Typical unit operations involved in wet granulation, dry granulation, and direct compression

Wet granulation	Dry granulation	Direct compression
Milling and mixing of drugs and excipients	Milling and mixing of drugs and excipients	Milling and mixing of drugs and excipients
Preparation of binder solution	Compression into slugs or roll compaction	Compression of tablets

3. Optimization of tablet disintegration

4. Stability

The most obvious advantage of direct compression is its greater economy, owing to reduced processing time, less equipment and space required, less process validation, and lower energy utilization. Generally, only blending and compression are required, although prior micronization of the drug may be needed. Unlike wet granulation, processing does not require heat or moisture, which can be detrimental to drug stability. Moreover, direct compression avoids the high pressures associated with slugging or roll compaction. In addition, disintegration is optimized because directly compressed tablets produce primary particles upon disintegration, rather than granules, which must deaggregate to liberate primary particles. Finally, direct compression tablets often exhibit fewer long-term problems of chemical stability or changes in dissolution.

Although there are many significant advantages of direct compression over granulation, there also are important limitations:

1. Uniform blending and prevention of unblending of low-dose drugs
2. Fillers often are costlier than fillers used in granulation
3. Physical properties and functional specifications are more critical; properties of raw materials must be defined and carefully controlled
4. Limitations in producing colored tablets
5. Dust problems
6. Limitations in the dilution capacity of fillet-binders
7. More sensitive to lubricant softening and overmixing than granulations

Limitations in the dilution capacity of excipients can make the direct compression of large-dose, poorly compactible drugs impractical. Lubrication is often

Table 2 Advantages and disadvantages of wet granulation

Advantages	Disadvantages
Enhances fluidity and compactibility. suitable for high-dose drugs with poor flow and/or compactibility	Each unit process brings its own set of complications
Reduces air entrapment	The large number of unit processes increases the chances of problems
Reduces dustiness	Difficult to control and validate
Provides for the addition of a liquid phase (wet granulation) suited to dispersion of low-dose drugs in solution to ensure content uniformity	Potential adverse effects of temperature, time, and rate of drying on drug stability and distribution during drying
Enhances wettability of powders through hydrophilization (wet granulation)	Overall more costly than direct compression in terms of space, time, and equipment requirements
Permits handling of powders without loss of blend quality	

a compromise between the amount and type needed for adequate lubrication and their adverse effect on compactibility. Content uniformity is of greater concern in direct compression tableting, particularly with low-dose drugs. Since the drug is not “locked” into granules, direct compression blends are subject to unmixing in subsequent processing steps. In addition, drugs are often micronized prior to blending to enhance their dissolution rate, and the resulting high surface-to-mass ratios may lead to difficulty in flowing and mixing due to surface interactions. Another important limitation is that unlike granulation, which tends to compensate for variability in excipients, direct compression is heavily dependent upon reproducible properties of the excipients (and the drug). Raw material standards must be carefully defined and address functionality. Lot-to-lot variations in both the drug and the excipients must be avoided. The cost of raw materials and their testing is higher in direct compression.

Thus, direct-compression tableting requires careful attention to the choice of excipients, appropriate flow properties, and blend homogeneity, and to the interplay of formulation and process variables that can affect both compactibility and drug dissolution. See also Direct Compression Tableting by R.F. Shangraw, Vol.4, (1st Ed.) pp. 85–106, of this encyclopedia.

Excipients

The design of the formulation and selection of excipients is especially critical in tablet dosage forms. Products can vary from a relatively simple aspirin tablet containing aspirin and starch to more complex systems that might contain fillers, binders, disintegrating agents, glidants, lubricants, and coating agents. Modified release introduces even more complexity. The appropriate selection of excipients and their concentration are clearly critical to both the ability to manufacture tablets as well as to their performance as a drug delivery system. Since others have illuminated the various excipient classes in great detail, references are provided in Table 3.

Manufacturability

Excipients function to provide compactibility, lubrication, flow properties, disintegration efficiency, wetting, etc. Poor choice of excipients may give rise to poor characteristics (hardness, appearance), which can be important in packaging, storage, and patient acceptance. Problems with excipients may arise from variations in source or lot, particularly in formulations made by direct compression. Examples of excipient problems include variation in performance between *Hoc* cellulose and microcrystalline cellulose relative to particle size, flow, and compactibility,

or different polymorphic forms of sorbitol (α , β and γ) resulting in tablet hardening. Differences in lactose particle size and modification (spray-dried or anhydrous) can provide differences in surface areas over which a lubricant is distributed. Anhydrous lactose hydrates at high humidities with increase in size.

Biopharmaceutics

The formulation of a tablet can affect its bioavailability. Particular care should be given to low-dose poorly soluble drugs, especially those that are micronized. Drugs with low water solubility should never be formulated solely with insoluble fillers, including calcium salts (calcium sulfate, calcium phosphate) which are only soluble at very low pH. Differences in solution rate between hydrated and nonhydrated forms of calcium salts as well as between dibasic and tribasic forms may also be important. In some cases, excipients complex with drug substances such as calcium salts with tetracycline. Varying the ratio of soluble to insoluble fillers in tablets can significantly alter the dissolution pattern of poorly soluble drugs (weak acids and nonelectrolytes), but has little effect on weak bases, which are soluble in gastric fluids.

The type and amount of disintegrating agent can also be important. Differences in source (corn, potato, rice) as well as variations in amylopectin–amylose ratios result in variable disintegration times. The fact that starch included within granules is not as effective as starch added between granules has led to tablets with good disintegration but poor dissolution. Incorporation of super-disintegrants (croscopovidone, croscarmellose, sodium starch glycolate) has improved dissolution from both direct-compression and wet-granulation formulations. Both croscarmellose and sodium starch glycolate can complex with small amounts of cationic drugs in water, but not in physiologic fluids (23).

The type and amount of binder used in granulations affects dissolution rates. Many binders are hydrophilic polymers whose solubility and solubility rate depend upon molecular weight. Quality control tests such as viscosity may be necessary as part of raw material testing of polymeric substances. However, an advantage of the granulation process is that it results in a wetting of drug surfaces, which enhances drug dissolution once the granules have disintegrated. Wetting agents such as sodium lauryl sulfate can significantly improve the dissolution of drugs of poor water solubility formulated into direct compression tablets.

Perhaps the greatest source of concern in excipients is with lubricants, particularly magnesium stearate, which is not only hydrophobic but also has a laminar crystal structure. When blended with other ingredients, it tends to

make them hydrophobic by delaminating to coat their surfaces. The problems with magnesium stearate are thus highly process dependent. For example, blending time differences of as little as 2 min can significantly alter the dissolution pattern of finished tablets. Because direct-compression formulations have a higher specific surface area, the same amount of magnesium stearate blended for the same length of time makes direct-compression tablet matrices more hydrophobic than matrices made from granulations. The degree of shear imparted by different mixers during processing significantly affects the distribution of magnesium stearate (24). The characteristics of magnesium stearate vary from supplier to supplier and sometime within the same supplier (25). It is essential to draft raw material specifications and strictly adhere to Standard Operating Procedures (SOPs) during the manufacture of products containing this lubricant. Establishing purchasing specifications beyond those listed in the *National Formulary*, such as bulk and tap density, powder fluidity, particle size, surface area, degree of hydration, and morphology is desirable.

THE EFFECTS OF MANUFACTURING PROCESSES ON FORMULATIONS

Numerous unit processes are involved in making tablets, including particle size reduction and sizing, blending,

granulating, drying, compaction, and (frequently) coating. Various factors associated with these processes can seriously affect content uniformity, bioavailability, or stability. Some of these are given in the following list:

1. Particle Size Reduction
 - Nonuniform particle size can lead to segregation problems
 - Development of electrostatic forces inhibits complete blending
 - Changing the crystalline state can affect solubility
2. Blending
 - Nonhomogeneous distribution of drug substance is the result of poor blending or unblending
 - Overblending of lubricant lowers dissolution rates and affects compactibility
3. Granulation
 - Nonhomogeneous distribution of binder and drug substance gives drug-rich or drug-poor fines
 - Decomposition of drug substance due to residual moisture
 - Uneven granule size (too many or too few fines) leads to compaction or uniformity problems
4. Tableting
 - Uneven compaction pressures affect dissolution
 - Loss of mix quality in hopper and feed frame gives poor content uniformity
 - Additional shearing of lubricant in feed frame lowers dissolution rates

5. Coating

- Nonuniform or incomplete coverage of tablets and beads results in different dissolution patterns

When validating new equipment or procedures, the sampling techniques must reflect the quality of the material being tested, the blend of powders, moisture in granulation, or coating integrity.

Another potential source of problems in manufacturing is reprocessing or reworking. Reworking may be required when finished products fail to meet hardness, content uniformity, disintegration, dissolution, or appearance specifications. Reworking procedures must be in writing and are often part of New Drug Applications (NDAs) and Abbreviated New Drug Applications (ANDAs). Although practiced less today than in past years, given the high cost of some drug substances, reworking continues to be justified, but may involve the following problems: overdistribution of lubricant leading to poor compactibility and dissolution; distribution of particles of coating in the reprocessed tablet may lower the dissolution rate; and loss in compactibility due to work hardening of direct-compression fillers, particularly at higher initial compaction pressures. Reworking is less likely to cause dissolution problems with water-soluble drugs.

SYSTEMATIC FORMULATION DEVELOPMENT

Previously, pharmaceutical experimenters were rarely afforded the luxury of using expanded experimental designs. Time and manpower constraints, imposed by an ever-quicken pace to market, have prevented the thorough examination and full understanding of most commercial formulations. Although the pace of formulating pharmaceutical systems has not lessened recently, a rapid turnaround means formulators must quickly gather information and base final decisions on that information. The window for error is narrower, and the formulator can no longer afford to use empirically gathered data to obtain the critical dosage form information needed for a marketable formulation. Systematic development approaches are also desirable to provide data in anticipation of the use of SUPAC (scale up and postapproval changes) regulatory policies by providing for the establishment of a research database that can help justify such changes to regulatory agencies.

Enormous progress has been made in the direction of systematic formulation development through the use of

such statistical tools as multivariate analysis and response surface methodology, and artificial intelligence.

Experimental Design

In the long term, an efficient experimental design saves time and avoids costly mistakes, and some pharmaceutical firms have departments devoted to the preparation of experimental designs and their analysis. If a statistician is not available, a myriad of commercial experimental-design software packages are on the market (SAS, JMP, STATGRAPHICS, DESIGN EXPERT) with which a formulator can design experiments on a personal computer. These same packages can also aid in data analysis and presentation.

The early phase of such a statistical experimental design approach may include screening designs such as two-level full or fractional factorial designs or Plackett-Burman designs. The number of experimental runs is reduced by intentionally confounding some experimental effects. Ultimately, the screening design narrows the number of potential variables for further study.

The latter phase of such as a central experimental design approach might include response surface methodologies to optimize a formulation such as a central composite or Box-Behnken design. Such methods allow experimenters to assess the effects of several variables at one time without having to study every possible unique combination of variables. This way, a systematic identification of critical variables and an optimization of the formulation and process can be obtained. Response surfaces are generated, which give formulators a graphic demonstration of the effect of variables on various responses, such as drug dissolution. The designs and models available to experimenters are numerous and the proper choice depends on the number of variables and the possible responses. General references for experimental design can be consulted as well as design software manuals, if a statistician is not available for advice.

Artificial Intelligence Approaches

Among the artificial intelligence approaches that have been used to provide support for the formulation process are expert systems and artificial neural networks. An expert system (ES) is an intelligent computer program that attempts to capture the expertise of specialists who have knowledge and experience in a well-defined domain. They are designed to simulate an expert's problem solving process. Developed more than 20 years ago for other

applications, expert systems are a relatively new idea in pharmaceutical technology. In rule-based systems, the knowledge is highly structured and often represented as a set of rules that express the relationship between several pieces of information in the form of conditional statements. These statements specify actions to be taken or advice to be followed. Such systems can shorten development time, simplify formulations, provide the rationale for decisions taken in arriving at a formulation, serve as excellent teaching tools for novices, and accumulate and preserve the knowledge and experience of experts. ESs suffer from the limitation that they are not creative. They can only deal with situations that have been anticipated. They must be designed to handle every contingency. Examples include expert systems developed for formulating tablets (26), for process troubleshooting (27), and for the selection of a mixer (28).

Used in other disciplines for about 40 years, artificial neural networks (ANNs), like ESs, have only recently been applied to pharmaceutical development. ANNs are computer-based programs that attempt to simulate certain functions of the biological brain, such as learning, generalizing, or abstracting from experience. They have the ability to discern relationships or patterns in response to exposure to facts ("learning."). ANN models may be viewed simply as multiple nonlinear regression models. Through ANNs, the data and information generated during experimental work may be transformed relatively easily into knowledge that would enable the formulator to at least construct a few domain specific rules, even though confined, for future cases. However, ANN effectiveness is limited by the training data selected. One limitation is that, in most cases, ANNs lack explanation capability and there is difficulty in obtaining justification for results. Examples of applications to product development include predicting model granulation and tablet characteristics from knowledge of material and process variables (29), and predicting drug release from immediate release formulations (30). The development of a hybrid system, i.e. an Expert Network, that integrates ANNs and ESs has the potential of taking advantage of the strengths of both ANNs and ESs and avoiding the weaknesses of either (31, 32).

Formulation Development

Whether working in a large established laboratory or a small research organization, formulators are well advised to take an overall look at the development process to assess the most rational approach to their particular needs and resources. Among many approaches to rational tablet formulation, the strategy used by researchers at the

University of Maryland in collaboration with FDA scientists (33) examines the drug product development process in light of the SUPAC guidance.

This generalized plan focuses on the assessment the possible influence of formulation and processing variables on bioavailability and manufacture. The research protocol is best visualized by the flow chart in Fig. 1. The model begins with the preformulation stage wherein information is obtained on the physicochemical and biopharmaceutic properties of the drug. One outcome of the preformulation study should be the identification of the biopharmaceutic class (BCS) in which the drug falls since this will provide important guidance in making formulation decisions. For multi-sourced drugs, the different sources are considered. The preformulation study results in a portfolio of information, which provides guidance in formulation design and in the development of appropriate hypotheses to be tested and the critical variables studies that follow.

In the critical variables analysis phase, a statistical experimental design is created (e.g., factorial, Box–Behnken) intended to assess critical formulation and process variables in relatively small-scale manufacture. In these studies, the ranges of composition variables are chosen to at least encompass those noted in the recommendations of the AAPS–FDA Workshop on Scale-up of

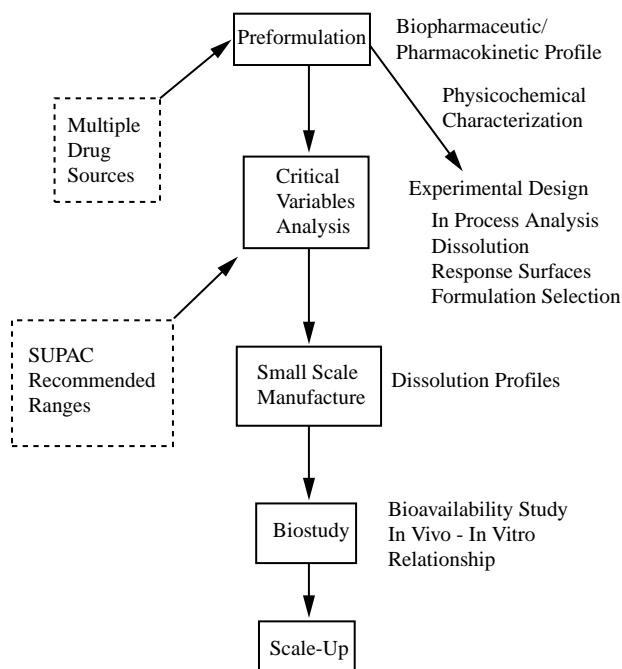

Fig. 1 A research model used in a University of Maryland and FDA collaborative research program. (From Ref. 33.)

Immediate Release Oral Solid Dosage Forms or SUPAC. This phase is usually preceded by a development phase during which variables and levels to be studied are determined and the exact method of manufacture is established. Experimental formulations are assessed at least in terms of dissolution performance, content uniformity, and weight variation. On the basis of these studies, the specific formulations to be manufactured for biostudy are selected.

In the small-scale clinical manufacturing phase, formulations are manufactured under GMP conditions for possible clinical testing. These will be manufactured on a larger scale than those in the previous phases. An experimental design is chosen; however, if some of the variables can be eliminated based on the earlier experiments, the number of formulations produced may be reduced.

The intent of the biostudy phase is to establish an in vitro–in vivo relationship. If an appropriate correlation can be established, dissolution may serve as a surrogate for biostudies in the interpretation of what is significant and what is not among the variables studied.

In the scale-up phase, larger runs of formulations are manufactured. The formulations are selected to determine if the larger scale will enhance the significance of certain variables.

The statistical analysis of the data provides the opportunity to predict changes in dissolution performance resulting from incremental changes in one or more formulation or process variable at a time (e.g., the level of an excipient or the time of mixing).

The development model presented here may differ from some formulation research programs in that biostudies may not be performed on small-scale batches. The major advantage of early biostudies is the potential for early IVIVC and subsequent surrogate use of dissolution testing in further work. Scale-up and pilot-plant roles in formulation changes, while not covered thoroughly here, are reviewed by Racz (34).

TABLET MANUFACTURE

Norman Anthony Armstrong

Cardiff University, Cardiff, United Kingdom

INTRODUCTION

The compressed tablet is by far the most widely used dosage form, having advantages for both producer and user. However, the manufacture of tablets can be a complex process, since only a few raw materials inherently possess those properties which are necessary for the production of tablets of satisfactory quality. Hence some preliminary treatment and/or incorporation of excipients in the formulation is usually needed. Tablet manufacture is a paradox. Considerable ingenuity and formulation expertise are required to transform a mass of particles into a low porosity mass. Yet, after the tablet has been ingested, the requirement then is usually for the tablet to release its active ingredient as rapidly as possible, and further ingenuity is needed to bring this about.

Tablets are solid preparations each of which contains a single dose of one or more active ingredients. They are obtained by compressing uniform volumes of particles, and are almost always intended for oral administration.

The earliest reference to a dosage form resembling the tablet is to be found in tenth century Arabic medical literature. Drug particles were compressed between the ends of engraved ebony rods, force being applied by means of a hammer. Details of the tableting process, as it is now known, were first published in 1843 when William Brockedon was granted British Patent 9977 for "manufacturing pills and medicinal lozenges by causing materials when in a state of granulation, dust or powder, to be made into form and solidified by pressure in dies." In this case, too, force was applied by a hammer. Potassium bicarbonate was the first pharmaceutical substance to be so treated.

The use of compressed pills, as they were then known, increased rapidly. It is likely that the term "tablet" for this dosage form was first used in the United States in the 1870s. Power-driven presses replaced Brockedon's hammer, and by 1874 there existed both rotary and excentric presses, which in their mode of operation were fundamentally similar to those in use at the present time. The tablet lent itself to mass manufacture by mechanical means, in contrast to the slower labour-intensive production of older solid dosage forms such as the pill. It is impractical for individual pharmacists to produce

small quantities of tablets on a commercial scale, and this led to the concentration of pharmaceutical manufacture in relatively few industrial sites.

A monograph for Glyceryl Trinitrate Tablets was included in the British Pharmacopoeia of 1885, but no other tablet monograph appeared there until 1945. This was not due to lack of popularity of the dosage form itself, but rather the absence of suitable methods of quality control that were applicable to tablets.

The tablet did not meet with universal approval. In 1895 an editorial in the *Pharmaceutical Journal* in the United Kingdom described the tablet as "one of the evils suffered by legitimate pharmacy," and predicted that tablets "have had their day" (1). Notwithstanding such a prediction, the usage of tablets has continued to increase. The 2000 edition of the British Pharmacopoeia contains 320 monographs for tablets, far in excess of any other dosage form.

The tablet is the most popular dosage form because it provides advantages for all concerned in the production and consumption of medicinal products. Though the initial capital outlay for the manufacturer of tablets is considerable, they can be produced at a much higher rate than any other dosage form, tablet presses capable of producing about one million tablets per hour being available. Furthermore, the fact that the tablet is a dry dosage form promotes stability, and in general, tablets have shelf lives measured in years. They are also convenient to transport in bulk, since they contain relatively small proportions of excipients unlike, for example, oral liquids.

From the viewpoint of the pharmacist, tablets are easy to dispense, while the patient receives a concentrated and readily transportable and consumed dosage form. Furthermore, if properly prepared, tablets provide a uniformity of dosage greater than that of most other medicines, and appropriate coating can mask unpleasant tastes and improve patient acceptance.

The tablet also provides a versatile drug delivery system. Though most tablets are intended to be swallowed intact, the same basic manufacturing process, associated with appropriate formulation, provides medicines for sublingual, buccal, rectal, and vaginal administration, together with lozenges, soluble, dispersible, and effervescent tablets. In addition, techniques that can delay or

otherwise modify the release of the active ingredient from the tablet are available.

Naturally tablets only possess these advantages if they are properly formulated and manufactured. A well-prepared tablet should possess the following qualities:

1. It should, within permitted limits, contain the stated dose of drug.
2. It should be sufficiently strong to withstand the stresses of manufacture, transport, and handling so as to reach the patient intact.
3. It should deliver its dose of drug at the site and at the speed required.
4. Its size, taste, and appearance should not detract from its acceptability by the patient.

TABLET COMPRESSION

All tablets are made by a process of compression. Solid, in the form of relatively small particles, is contained in a die and a compressing force of several tonnes is applied to it by means of punches. The shape of the die governs the cross-sectional shape of the tablet, and the distance between the punch tips at the point of maximum compression governs its thickness. The conformation of the tablet faces, usually flat or convex, is a reflection of those of the punches.

The tip of the lower punch moves up and down within the die, but never actually leaves it. The upper punch descends to penetrate the die and apply the compressive force. It is then withdrawn to permit ejection of the tablet, brought about by an upward movement of the lower punch.

There are two types of tablet press. The excentric press has one die and one pair of punches. The rotary press has a larger number of dies which are fitted, with their corresponding punches, into a rotating turret.

Irrespective of the type of press that is used, the process of tablet compression can be divided into three stages, as shown in Fig. 1.

Stage 1, Filling

The lower punch falls within the die, leaving a cavity into which particulate matter flows under the influence of gravity from a hopper. Though tablets are usually described in terms of weight, the die is filled by a volumetric process. The volume is determined by the depth to which the lower punch descends in the die. Unless this volume is filled reproducibly on each occasion, then

Fig. 1 Cycle of operations of an excentric tablet press.

the mass of the tablet will vary, and with it the drug content of each tablet. Therefore, uniform filling is essential. However, it must be borne in mind that the die cavity has a cross-section of only a few millimetres, and only a fraction of a second is available for filling each die. It therefore follows that the particles must flow easily and reproducibly.

Stage 2, Compression

The upper punch descends, and its tip enters the die, confining the particles. The distance separating the punch faces decreases, either by movement of the upper punch alone (as in excentric presses) or by movement of both punches (as happens in rotary presses). The porosity of the contents of the die is progressively reduced, and the particles are forced into ever-closer proximity to each other. This process is facilitated by the particles fragmenting and/or deforming. Once the particles are close enough together, interparticulate forces then cause the individual particles to aggregate, forming a tablet. The magnitude of the force is governed by the minimum distance separating the punch faces. Therefore, a second essential property of the particles is that they cohere under the influence of a compressive force. It is also essential that this coherence be maintained when the compressing force is removed.

Stage 3, Ejection

The upper punch is withdrawn from the die, and so the force being applied to the tablet is removed. The effect of this might be to cause the deformed particles to return to their former shape, which would result in a decrease in interparticulate contact and hence tablet strength. It is essential that this does not occur. As the upper punch leaves the die, the lower punch moves upwards, pushing the tablet before it. During the compression stage, the particles are forced into intimate contact with the interior die wall. It follows that attempts to remove the tablet will be opposed

by frictional forces and so successful ejection demands lack of adhesion between the tablet and the die wall.

Therefore in summary, for a particulate solid to be successfully transformed into tablets, three key properties need to be present:

1. Good particle flow.
2. The ability of the particles to cohere under the influence of a compressing force. This coherence must be retained after the compressing force has been removed.
3. The ability of the tablet to be ejected from the die after the compressing force has been removed.

Few powders possess all these essentials and some possess none of them. Thus, before successful tableting can take place, some preliminary treatment with the addition of one or more excipients is almost invariably needed.

METHODS OF TABLET PRODUCTION

The pretreatment that is usually necessary takes the form of granulation. The process of granulation is essentially one of size enlargement, and it serves several purposes in the tablet manufacturing process:

1. It improves flow by increasing particle size, since large particles flow more readily than small ones.
2. It improves compression characteristics, adding to the cohesive strength of the tablet.
3. Once a homogeneous mixture has been achieved, segregation is prevented, since particles that are stuck together cannot separate.
4. It reduces dust.

Both wet and dry granulation techniques are available.

Tablet Manufacture by Wet Granulation

This is the traditional method of pretreatment of solids prior to tableting. Despite its complexity and inherent disadvantages, even now about half the tablets produced worldwide are manufactured by this process. Its essence is that particles of active ingredient, with a diluent if necessary, are stuck together using an adhesive, the latter usually being water-based. The result is a granular product which flows more readily and has an improved ability to cohere during compression.

A flow diagram of the wet granulation process together with appropriate excipients is shown in Fig. 2.

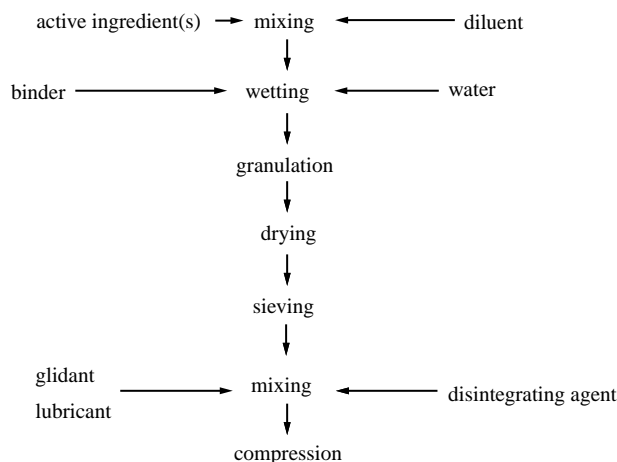

Fig. 2 The wet granulation process of tablet manufacture.

The diluent

The first stage in the wet granulation process is often a dry mixing stage in which the active component is mixed with a diluent. Many drugs need to be administered in doses of only a few milligrams or even less, yet a tablet that weighs less than about 50 mg is difficult for the patient to handle conveniently. It is therefore necessary to increase the bulk of such a tablet with a diluent. Some commonly used diluents are listed in Table 1.

The ideal diluent would be both chemically and physiologically inert, and would not interfere with the bioavailability of the active ingredient. It should also be inexpensive and be easily tableted since, if the proportion of active ingredient is small, the overall tableting properties of the mixture are largely governed by those of the diluent.

Lactose is by far the most frequently used diluent for solid dosage forms. An inexpensive disaccharide obtained as a by-product of the cheese industry; it is available in a number of forms, though α -Lactose monohydrate is the variety that is normally used as the diluent in tablets made by wet granulation. It is freely albeit slowly soluble in water and as such it is a suitable diluent for active ingredients of low water solubility. Lactose is a nonreducing sugar, and is reasonably inert. It can take part in the Maillard reaction when mixed with substances containing primary amine groups, giving highly colored products, and thus its use is contraindicated in such formulations (2).

Probably the second most commonly used diluent in the wet granulation process is dibasic calcium phosphate. This substance is virtually insoluble in water and hence is always used in conjunction with a disintegrating agent. Its properties have been reviewed by Carstensen and Ertell (3).

Table 1 Tablet diluents

Diluent	Comments
Calcium carbonate	Insoluble in water (Cal-Carb ^R , Millicarb ^R , Pharma-Carb ^R , Sturcal ^R)
Calcium phosphate, dibasic	Insoluble in water, good flow properties, available in dihydrate and anhydrous forms (Cyfos ^R , Calstar ^R , Calipharm ^R , Emcompress ^R)
Calcium phosphate, tribasic	Insoluble in water (Tricafos ^R , Tri-Cal ^R , Tri-Tab ^R)
Calcium sulfate	Insoluble in water (Cal-Tab ^R , Compactrol ^R)
Cellulose, microcrystalline	Good compression properties, may not need lubricant, can act as disintegrant (Avicel ^R , Emcocel ^R , Vivacel ^R)
Cellulose, microcrystalline silicified	Combination of microcrystalline cellulose and silica (Prosolv ^R)
Cellulose, powdered	(Elcema ^R , Solka-Floc ^R)
Dextrates	(Emdex ^R)
Dextrose	Hygroscopic, reducing sugar (Tabfine ^R)
Fructose	(Fructofin ^R)
Lactitol	(Finlac ^R)
Lactose monohydrate	The most commonly used diluent. Inexpensive, takes part in Maillard reaction (Fast-Flo ^R , Lactochem ^R , Microtose ^R , Pharmatose ^R , Tablettose ^R , Zeparox ^R)
Magnesium carbonate	
Maltitol	(Maltisorb ^R , Maltit ^R)
Maltodextrin	(Glycidex ^R , Lycatab ^R , Maltrin ^R)
Maltose	(Advantose ^R)
Mannitol	Freely soluble in water, negative heat of solution and therefore cool taste, popular for chewable tablets, noncariogenic (Pearlitol ^R)
Sodium chloride	Freely soluble in water, used in solution tablets
Sorbitol	
Starch	Also acts as disintegrating agent, may give soft tablets
Starch, pregelatinized	Also acts as disintegrating agent. (Lycatab ^R , Pharma-Gel ^R , Pre-Jel ^R , Sepistab ^R , Starch 1500 ^R , Starx 1500 ^R)
Sucrose	Freely soluble in water, sweet taste, hygroscopic, used in lozenges in conjunction with lactose
Sugar, compressible	(Dipac ^R , Nutab ^R)
Sugar, confectioner's	
Sugar spheres	(Nu-Core ^R , Nu-Pareil ^R)
Talc	
Xylitol	Negative heat of solution, cool taste (Xylifin ^R , Xylitab ^R)

Proprietary names are given in parentheses.

Mixing

The purpose of the mixing stage is to ensure that the powder blend and hence the resulting tablets are homogeneous in content. A random mixture is defined as one where the probability of sampling a given type of particle is proportional to the number of such particles in the total mixture. Thus, the aim is to produce a mixture such that when a sample is removed, the relative proportions of the components of that sample are the same as in the mixture as a whole.

Unlike molecules in a fluid, which in time will mix spontaneously by a diffusion mechanism, powder particles do not mix spontaneously but remain in their relative

positions. Therefore before mixing can occur, energy must be put into the system. This causes the powder bed to dilate or expand, the particles separate from one another and this leads to relative motion among them.

It might be intuitively expected that the randomness of a mixture will progressively increase with time, but this is not always the case. Under certain conditions, an optimum mixing time occurs, beyond which the mixture shows a tendency to separate back into its components. This process is known as segregation. Segregation is particularly likely to occur in mixtures where the components differ markedly in size, with differences in shape and density as secondary factors. It is especially likely to occur if regular patterns of movement are set up in the mixing

device, and for this reason, mixers are designed so that an irregular mixing motion occurs (4).

Although in general a size difference between components can lead to segregation, a situation where there is a large difference in sizes between components may be beneficial. In such circumstances, small particles of one component can become trapped in irregularities in the surface of the larger component. These are not random mixtures, as the particles of the two components cannot behave independently. This concept is called "ordered mixing" and it has found applicability in the manufacture of solid dosage forms containing small quantities of highly potent active ingredients (5) (see the article on Blenders and Blending in this encyclopedia).

Granulation

The underlying process of size enlargement in wet granulation is achieved by either one or both of two different mechanisms. Firstly, adjacent solid particles may be stuck together using an adhesive. Such substances are known as binders or granulating agents. Secondly, dissolution of the solid in the granulating liquid can occur, followed by evaporation of the liquid phase of the latter. This will result in the deposition of dissolved material on particle surfaces, forming so-called crystal bridges. The occurrence of this mechanism will depend on the solubility of the solids in the liquid phase. Thus, sucrose will form crystal bridges with an aqueous granulating fluid, whereas calcium phosphate will not.

The process and underlying mechanisms of granulation have been fully described by Sherrington and Oliver (6). Details of commonly used binders are given in Table 2. They are often natural or synthetic polymers and are usually added as aqueous solutions or dispersions. Alternatively, they can be mixed with the other solids in the formulation in the dry state, water then being added.

If the active ingredient is unstable in the presence of water, then a granulation process using nonaqueous liquids can be used. The usual granulating system in such cases is povidone dissolved in isopropanol. The extra costs and environmental problems posed by the use of a volatile and flammable liquid are disincentives to the use of nonaqueous granulation.

The traditional piece of granulating apparatus is the shear granulator. Its function is to homogeneously incorporate an adhesive and viscous liquid such as starch paste into a mass of dry powder to form agglomerates. It follows that a considerable shearing force needs to be exerted. The mixed solids are loaded into the bowl of the mixer, and the liquid added with agitation. The damp solid is then forced through a relatively coarse screen (about 1–2 mm), often by means of oscillating bars, to give

discrete granules. The progression of the granulation process can be monitored by measuring the electrical power consumption by the granulator, and hence optimum granulation times can be established. Ertell et al. have shown that the size of the granulator and the mixing time can be major influences on the physical properties and dissolution rate of the resulting tablets (7).

As described above, the wet granulation process is a long and hence expensive procedure, which has been improved by the introduction of high-speed mixer granulators. These have agitator and chopping blades, which enable mixing, wet massing, and granulation to take place in the same piece of apparatus. In such devices, the granulation process takes place extremely rapidly, and hence the establishment of optimum granulation times is even more important.

A further technique is fluid-bed granulation. Air is passed into the powder bed from below. This causes the particle, of powder to form a suspension in the air and gives effective mixing. The granulating fluid is then sprayed over the particles, which adhere on collision and they are then dried in the heated air stream.

The wet granulation process, apparatus, and pharmaceutical applications have been comprehensively reviewed by Kristensen and Schaefer (8) (see the article on Tablet Granulation in this encyclopedia).

Drying

After the process of granulation, the product exists as a wet mass from which the liquid must be removed, since the presence of water leads to the impairment of flow properties, and perhaps to chemical instability. Water is usually removed by evaporation for which energy is needed. This is normally provided as heat, though microwave energy is being increasingly used for drying in tablet manufacture.

The essential constituents of an effective piece of drying equipment are a heat supply to increase the temperature and thereby reduce relative humidity, a device for removal of evaporated water and a means of minimizing the distance that water molecules must diffuse before they can be evaporated.

The fluidized bed drier is the most commonly used device for drying tablet granules. The solid is fluidized from below by a jet of hot air, and so each granule becomes separated from its neighbors. The air provides an effective means of heat transfer, as well as of removing water vapor. The speed of the drying process is governed by the distance that water molecules must diffuse before they arrive at the evaporative surface. Since the wet granules are present as individual units, the maximum distance over which diffusion occurs is equal to the radius of a granule. Hence, fluidized bed drying is a rapid process.

Table 2 Binders used in the wet granulation process

Binder	Concentration in the granulating fluid (% w/v)	Comments
Acacia mucilage	Up to 20	Yields very hard granules
Alginic acid	1–5	
Carbomer	5–10	(Carbopol [®])
Carboxymethylcellulose calcium	5–15	(Nymcel [®])
Carboxymethylcellulose sodium	5–15	(Nymcel [®])
Cellulose, microcrystalline		(Avicel [®] , Emcocel [®] , Vivacel [®])
Powdered cellulose		(Elcema [®] , Solka Floc [®])
Ethyl cellulose	1–3	(Aquacoat [®])
Gelatin	5–20	Forms gel in cold water, therefore warm solution used, strong adhesive
Glucose, liquid	Up to 50	Strong adhesive, hygroscopic
Guar gum	1–10	
Hydroxyethyl cellulose	2–6	(Cellosize [®])
Hydroxypropyl cellulose	2–6	(Klucel [®] , Methocel [®])
Hydroxypropyl cellulose—low-substituted	5–25	
Hydroxypropylmethyl cellulose	2–5	(Methocel [®] , Pharmacoat [®])
Magnesium aluminum silicate	2–10	(Pharmasorb [®] , Veegum [®])
Maltodextrin	2–10	(Glucidex [®] , Lycatab [®] , Maltrin [®])
Methylcellulose	1–5	(Celacol [®] , Methocel [®])
Polydextrose		(Litesse [®])
Polyethylene oxide	5	(Polyox [®])
Povidone	0.5–5	Also known as PVP or polyvinylpyrrolidone. Soluble in water and some organic solvents, can be used for nonaqueous granulation, very commonly used, synthetic material (Kollidon [®] , Plasdone [®])
Sodium alginate	1–3	(Manucol [®])
Starch paste	5–25	Very commonly used
Starch, pregelatinized	5–10	(Lycatab [®] , Pharma-Gel [®] , Pre-Jel [®] , Sepistab [®] , Starch 1500 [®] , Starx 1500 [®])
Sucrose (syrup)	Up to 70	Hygroscopic, tablets may harden on storage
Water		Suitable for solids that are freely soluble in water

Proprietary names are given in parentheses.

The temperature of the bed can be precisely controlled, and a free-flowing product results. The resemblance to fluid-bed granulation will be apparent, and apparatus based on the fluidized bed principle is available in which mixing, granulation, and drying take place in the same chamber.

Although the apparent turbulence of the air stream may give rise to interparticulate collisions and hence attrition, this is not usually a severe problem. However, the rapid movement of particles in a hot, dry atmosphere can lead to the development of static electrical discharges. Suitable precautions must therefore be taken, especially if flammable liquids have been used in the granulation process.

A more traditional means of drying is the tray drier. Hot air flows over a series of shelves on which the wet material is spread. Compared to the fluidized bed drier, the solid–air interface is smaller, and water molecules may have to diffuse through the whole thickness of the solid layer before the evaporative surface is reached. Thinner layers give quicker evaporation, but this would reduce the overall capacity of the drier. Thus, the drying process is slower in a tray drier than in a fluidized bed drier.

As water diffuses through the bed of solid, it will carry with it any components of the formulation that are soluble in it. This will lead to a nonuniform distribution of these components in the solid. This is not usually a problem with

Table 3 Tablet glidants

Glidant	Concentration in tablet (%)	Comments
Calcium silicate	0.5–2	
Cellulose, powdered	1–2	(Elcema ^R , Solka Floc ^R)
Magnesium carbonate	1–3	
Magnesium oxide	1–3	
Magnesium silicate	0.5–2	
Silicon dioxide, colloidal	0.05–0.5	Excellent glidant (Aerosil ^R , Cab-o-Sil ^R)
Starch	2–10	
Talc	1–10	Insoluble in water but not hydrophobic

Proprietary names are given in parentheses.

fluidized bed drying, but with tray drying, significant differences in composition can occur between the upper and lower surfaces of the solid bed. This can give rise to nonuniform drug content and, if the migrating species is colored, variation in the appearance of the product (9, 10).

Microwaves are being increasingly employed in the pharmaceutical industry for drying purposes. The incident microwave radiation (frequencies of 2450 and 960 MHz are used) causes electrons in substances such as water to resonate, which in turn generates heat and causes the water to evaporate. The water vapor is removed under vacuum, and hence the product dries rapidly at a relatively low temperature. As the bed of solid is stationary, particle attrition does not occur, and dust formation is minimized (see the article on Drying and Driers in this encyclopedia).

Second mixing stage

When the drying process is complete, it is likely that the product will have cohered into relatively large masses, especially if tray drying has been used. The dried material is therefore passed through a sieve (usually 250–700 μm) to break up aggregates and to give a relatively uniformly sized granule. A second mixing stage now follows in which several important ingredients of the formulation are added.

The glidant

The formation of granules from the original powder particles may have improved flow sufficiently for uniform die filling to be achieved. However, if flow is still not good enough, a glidant (also known as an anticaking agent) can be added to improve flow still further.

The most frequently used glidant is colloidal silicon dioxide, which has a mean size of about 20 nm. It is thought to act by lodging in the surface irregularities of the granule, forming a more rounded structure and hence reducing interparticulate friction. Colloidal silica has the added advantage of acting as a moisture scavenger.

Residual water in the formulation is bound to the silica, thereby providing a drier environment for the other ingredients.

Methods of assessing glidant action have been reviewed by Augsburg and Shangraw (11). Lerk et al. showed that a concentration of 0.2% colloidal silica in a tablet formulation had no effect on tablet crushing strength. However, higher concentrations reduced crushing strength especially when associated with prolonged mixing times (12).

Some commonly used glidants are shown in Table 3.

The lubricant

When the tablet formulation is compressed, the sides of the tablet are brought into intimate contact with the die wall. The tablet must then be ejected from the die, involving the movement of the side of the tablet relative to the die wall. Therefore, friction between the tablet and the die wall must be overcome. With materials such as lactose, friction resistance can be considerable, and it may be impossible to remove the tablet from the die without damage to the tablet or to the tablet press. Therefore, a lubricant is almost invariably included in a tablet formulation. A lubricant is a substance that deforms easily when sheared between two surfaces, and hence when interposed between the tablet and the die wall, provides a readily deformable film (13).

Details of some tablet lubricants are shown in Table 4.

Inadequate lubrication can often be recognized by vertical scratches on the sides of the tablet. It may also lead to a build-up of solid on the punch faces, which in turn gives a matt, dimpled appearance to the face of the tablet, a phenomenon known as picking.

In practice, magnesium stearate is by far the most frequently used tablet lubricant, and is extremely effective. Its activity, as with other metallic salts of fatty acids, is believed to derive from adhesion of the polar metallic portion of the molecule to the powder particle surface.

Table 4 Tablet lubricants

Lubricant	Concentration in tablet (wt%)	Comments
Calcium stearate	0.5–2	Water insoluble
Fumaric acid	5	Water soluble
Glyceryl behenate	0.5–4	Water insoluble
Glyceryl palmitostearate	0.5–5.0	Water insoluble (Precirol ^R)
Hydrogenated vegetable oil	1–6	Water insoluble, may be used in conjunction with talc (Lubritab ^R , Sterotex ^R)
Magnesium lauryl sulfate	1–2	Soluble in warm water
Magnesium stearate	0.25–5	Water insoluble, excellent lubricant, reduces tablet strength, prolongs disintegration and dissolution times
Polyethylene glycol 4000 or 6000	2–5	Soluble in water, moderately effective, also known as macrogols (Carbowax ^R)
Sodium lauryl sulfate	1–2	Water soluble, moderate lubricant, but good wetting properties, often employed in conjunction with stearates (Empicol ^R , Stearowet C ^R)
Sodium stearyl fumarate	0.5–2.0	Sparsingly soluble in cold water, soluble in hot water (Pruv ^R)
Starch	2–10	Moderate lubricant
Stearic acid	1–3	Water insoluble
Talc	1–10	Insoluble in water but not hydrophobic. A moderate lubricant
Zinc stearate	0.5–2	Water insoluble

Proprietary names are given in parentheses.

As a consequence, the hydrocarbon portion of the molecule becomes oriented away from the surface (14). Thus, a nonpolar layer is presented to adjacent powder particles and structures such as the press tooling. It is from the formation of this nonpolar layer that the advantages and disadvantages of the use of magnesium stearate in a tablet arise.

To act as an effective lubricant in a tablet, the lubricant must be dispersed over the surface of the powder particles or granules. The more complete this layer, the more effective the lubricant action will be. However, this has two deleterious consequences. The first is that each powder particle presents a hydrophobic and hence water repellent exterior. It is well known that the presence of a lubricant based on fatty acids slows disintegration and dissolution, and has been shown to cause bioavailability problems.

The second consequence is that direct contact between powder particles is, at least in part, replaced by contact between adjacent hydrocarbon layers. Since these by definition have low shear strength, it is not surprising that interparticulate bonding is reduced and hence the tablet structure is weakened. Reduction in tablet strength is particularly marked with substances such as microcrystalline cellulose that undergo deformation on compression, since although the particles may change

shape, the hydrocarbon layer remains intact. Substances which fragment on compression suffer a smaller reduction in strength, since new surface, uncontaminated by lubricant, is created as the particles break up. This new surface can then take part in interparticulate bonding (15).

All these factors, both positive and negative, are consequences of the attrition of particles of lubricant and their spreading around the exterior surface of the other components of the tablet. Therefore, any processing factor that can affect lubricant attrition or the completeness of the film might be expected to influence tablet disintegration, dissolution, bioavailability, and physical strength. The mixing process is extremely important here, and mixing time, mixer type, and batch size (16) have all been shown to influence tablet properties. Thus, there is a need to establish a minimum lubricant concentration and an optimum mixing time within which adequate lubrication is achieved without the development of undesirable tablet characteristics. To ensure batch-to-batch uniformity, the parameters of the mixing process such as type of mixer, batch size, and mixing time must be kept as constant as possible. A mixing time of 2–5 min usually suffices to give adequate lubrication (17).

The water repellent properties of hydrocarbon based lubricants can be countered to a certain extent by the inclusion of a wetting agent such as sodium lauryl sulfate into the formulation. Such materials themselves can have a limited lubricant action. Mixtures of stearates and lauryl sulfates are commercially available.

Sodium stearyl fumarate has been used as an alternative for magnesium stearate. It has about the same lubricating effect, and causes similar tablet strength reduction and prolongation of disintegration time (18).

Lubricants based on fatty acids, because of their low water solubility, are unsuitable for tablets which must be dissolved in water before use. Polyethylene glycol 6000 (macrogol 6000) is soluble in water, but its lubricant activity is limited. Magnesium lauryl sulfate has been suggested as a water-soluble substitute for magnesium stearate. In addition to its lubricant action, this substance, like sodium lauryl sulfate, is an effective wetting agent (19).

It must be stressed that the functions of a glidant and lubricant in a tablet formulation are totally different. A few materials, e.g. talc, can act as both glidant and lubricant, but usually two different excipients are needed. Thus, although colloidal silicon dioxide is an excellent glidant, it has no lubricant activity. Conversely, magnesium stearate, despite its popularity as a lubricant, can hinder rather than promote flow.

The disintegrating agent

Strongly coherent particles are essential for the production of robust tablets, which will have high physical strength and low porosity. However, before it can be absorbed in the gastrointestinal tract, the active ingredient must dissolve, and a physically strong tablet is an impediment to dissolution. Therefore, tablet formulations often include a disintegrating agent, which when it comes into contact with water, disrupts the tablet structure and leads to fragmentation. A larger surface area is thus exposed to the dissolving fluid and dissolution is facilitated. Tablets which contain a large proportion of solids that are freely soluble in water have less need of a disintegrating agent, since such tablets tend to erode from their exterior surfaces rather than disintegrate.

Details of some tablet disintegrating agents are given in Table 5.

For many years, starch was the disintegrating agent of choice. Recently, however, so-called "super disintegrants" have been introduced, which markedly reduce tablet disintegration time. Such substances include croscarmellose, crospovidone, polacrillin potassium, and sodium starch glycolate (20).

The disintegrating agent may be mixed with other powders prior to wetting with the granulating fluid

(intragranular) or at the second mixing stage (extragranular), or both. Shotton and Leonard found that while extragranular disintegrating agents caused the tablet to disintegrate quicker, intragranular disintegrants not only broke down the tablet but also the constituent granules, giving a finer product (21).

The mechanism of action of disintegrating agents has been the subject of some debate (22). Some substances such as starch swell when they come into contact with water, and disruption of the tablet structure has been attributed to this. However, other effective disintegrants do not swell in this way, and are believed to act by providing a network of hydrophilic pathways inside the tablet through which water can diffuse. Irrespective of the precise mechanism of disintegration, it is clear that water uptake into the tablet must be the first step in the disintegration process (23).

Addition of wetting agents such as sodium lauryl sulfate or sodium docusate can assist this water penetration by lowering the surface tension, and they are often used in conjunction with hydrophobic lubricants such as magnesium stearate (see the article on Tablet Disintegrants and Disintegration in this encyclopedia).

Tablet Manufacture by Dry Granulation

Although widely used, the wet granulation method of tablet manufacture suffers from several disadvantages. Water is the usual granulating fluid, and this exposes tablet ingredients to the danger of hydrolysis. Furthermore, the granulating fluid has to be removed, usually by heating. In addition to the energy costs that are incurred, the elevated temperature will accelerate any hydrolytic reaction that might be taking place.

Dry granulation is an alternative method that can be used, and this process is shown in Fig. 3. The components of the formulation are compressed in the dry state. If sufficient bonding strength cannot be achieved by compression alone, a binder is added, also in the dry state.

The initial compression stage can take place by one of two methods. The first uses a conventional tablet press, a process often referred to as "slugging." Because the components of the formulation will not have the necessary attributes for producing good tablets, the tablets produced at this stage (the slugs) will not be of acceptable quality, especially as regards to appearance and weight uniformity. The slugs are then broken down to form a granular product, which after sieving can then be compressed again to give satisfactory tablets. Malkowska and Khan showed that the ease of compressibility of the formulation at the second compression was inversely proportional to

Table 5 Tablet disintegrating agents

Disintegrating agent	Concentration in tablet (wt %)	Comments
Alginic acid	2–10	
Carbon dioxide		Created in situ in effervescent tablets
Carboxymethylcellulose calcium	1–15	(Nymcel [®])
Carboxymethylcellulose sodium	1–5	(Nymcel [®])
Cellulose, microcrystalline	Up to 10	Directly compressible, some lubricant properties (Avicel [®] , Emcocel [®] , Vivacel [®])
Cellulose, powdered	5–15	Solka Floc [®]
Croscarmellose sodium	0.5–5	(Ac-di-Sol [®] , Solutab [®])
Crospovidone	2–5	(Kollidon CL [®] , Polyplasdone XL [®])
Docusate sodium	0.5–1	Acts primarily as a wetting agent
Guar gum	2–8	
Hydroxypropyl cellulose—low-substituted	5–25	
Magnesium aluminum silicate	2–10	(Veegum [®])
Methylcellulose	2–10	
Polacrillin potassium	2–10	Cation exchange resin (Amberlite IRP88 [®])
Poloxamer	5–10	
Povidone	0.5–5	(Kollidon [®] , Plasdone [®])
Sodium alginat	2.5–10	(Manucol [®])
Sodium glycine carbonate		Source of carbon dioxide for effervescent tablets
Sodium lauryl sulfate	0.5–2	Primarily a wetting agent but aids disintegration (Empicol [®])
Sodium starch glycolate	2–8	(Explotab [®] , Primojel [®])
Starch	2–10	Potato and maize starches are most frequently used
Starch, pregelatinized	5–10	(Lycatab [®] , Pharma-Gel [®] , Pre-Jel [®] , Sepistab [®] , Starch 1500 [®] , Starx 1500 [®])

Proprietary names are given in parentheses.

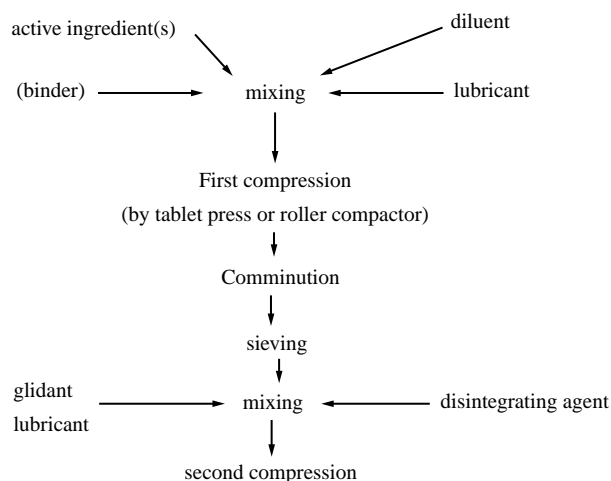

Fig. 3 The dry granulation process of tablet manufacture.

the pressure used at the slugging stage, implying that slugging at high pressure should be avoided (24).

A second method of compression is to use a roller compactor. The powder mixture is passed between two contra-rotating cylindrical rollers to form a cake, which as before is broken down to a product of granular size and then recompressed. Both methods require the addition of a lubricant prior to the first compression stage, though more lubricant will probably be needed before the second compression.

Tablet Manufacture by Direct Compression

Both wet and dry granulation methods of tablet manufacture are complex multistage processes, but are necessary to convert the components of the formulation into a state that can be readily compressed into acceptable tablets. If, however, a major component of the formulation already possesses the necessary degree of fluidity and compressibility, granulation would be unnecessary. This is the basis of the direct compression method of tablet manufacture (25).

The key component here is the diluent. This must not only possess those properties which are necessary for satisfactory tablet formulation, but also retain those properties when mixed with the other constituents of the formulation such as the active ingredient.

The process of direct compression is shown in Fig. 4. The ingredients are mixed together and then compressed. Almost invariably a lubricant must be added, and a glidant and a disintegrating agent included when necessary. The process does not involve the use of a liquid, and hence a drying stage with its attendant energy costs is avoided.

Fig. 4 The direct compression process of tablet manufacture.

Details of some direct compression diluents are given in Table 6. The majority of these are available from only one supplier, though the two most frequently used—spray-dried lactose and microcrystalline cellulose—are available from several sources.

In view of the apparent simplicity of this method of tablet manufacture and the number of suitable diluents that are commercially available, it is perhaps surprising that techniques of tablet manufacture involving granulation are still so widely used. Direct compression can, of course, only be used when a diluent is required by the formulation, i.e., the active ingredient must be relatively potent. Direct compression can offer significant savings in energy, equipment, and material handling costs. Against this must be set higher ingredient costs, since direct compression diluents are more expensive than other diluents.

There are, however, other factors which must be considered. In wet granulation, the properties of the individual drug and diluent particles are, at least to a certain extent, hidden by the binder, whereas in direct compression, the original particles are still present. Therefore, in the latter technique, a premium is placed on batch-to-batch consistency of particulate properties such as size and shape for both drug and diluent. In a direct compression formulation, the components can behave as individual particles, and therefore there is a danger that these can segregate after mixing and prior to compression. In a granulation process, the particles are bound together and so segregation is less likely to happen. Furthermore, the reduction in dust formation brought about by granulation cannot occur in direct compression.

The true direct compression process as described earlier almost invariably applies to formulations containing potent active ingredients and where the direct compression properties derive from the diluent. A few substances do possess adequate flow and cohesive properties without the need for pretreatment. These are usually crystalline inorganic salts such as sodium chloride and potassium chloride. Direct compression forms of less potent active ingredients are available e.g., paracetamol and ascorbic acid. These can be directly compressed into tablets, perhaps after the addition of a lubricant. However, such

Table 6 Direct compression tablet diluents

Diluent	Proprietary name	Comments
Calcium phosphate, dibasic	Emcompress ^R , Di-Tab ^R	Good flow properties, high density, insoluble in water
Calcium phosphate, tribasic	Tri-Tab ^R	Insoluble in water
Calcium sulfate	Compactrol ^R	Insoluble in water
Cellulose, microcrystalline	Avicel ^R , Emcocel ^R , Vivacel ^R	Highly compressible, low bulk density, acts as disintegrant
Cellulose, powdered	Elcema ^R	
Dextrates	Emdex ^R	
Lactitol	Finlac ^R DC	
Lactose		
Anhydrous alpha	Pharmatose DCL30 ^R	Good flow properties
Anhydrous beta	Pharmatose DCL21 ^R	
Spray-dried	Fast-Flo ^R , Zeparox ^R , Pharmatose DCL11 ^R	
Lactose-cellulose coprocessed mixture	Cellactose ^R	
Maltodextrin	Lycatab ^R , Maltrin ^R	Fairly soluble in water, slight lubricant effect
Mannitol	Pearlitol ^R	Freely soluble in water, negative heat of solution
Sorbitol	Neosorb ^R	
Starch, pregelatinized starch	Starch 1500 ^R , Starx 1500 ^R	Disintegrant
Sucrose–maltodextrin coprecipitate	Des-Tab ^R , Dipac ^R , Nu-Tab ^R	Good flow properties, moisture sensitive
Xylitol	Xylitab ^R	Freely soluble in water, negative heat of solution

substances are more accurately described as “pre-granulated,” in that the granulation process—either wet granulation or precompression—has been carried out by the excipient manufacturer (see the article on Direct Compression Tableting in this encyclopedia).

THE BEHAVIOR OF PARTICLES UNDER A COMPRESSIVE LOAD

All tablet manufacture can be regarded as the application of pressure to a population of particles enclosed in a confined space. An understanding of particle behavior under such conditions is therefore the key to understanding the formation and properties of tablets.

Application of a Force to Particles in a Die

Attractive forces exist between any two solid bodies. These forces may be nonspecific, e.g., van der Waal's forces, or may be more specific in nature, e.g., brought about by molecules exhibiting intermolecular hydrogen bonds. However, irrespective of their nature, it is these

forces acting among a large population of particles that enable a coherent tablet to be formed (26). Their magnitude depends directly on the particle mass and inversely on the square of the distance separating the particles. It follows, therefore, that with small particles of small mass, a tablet will only be formed when adjacent particles are forced into intimate contact with each other. This contact is brought about by the application of force.

A representation of what may happen to an individual particle when a force is applied to it can be obtained by considering what happens to a spring when subjected to a load that is applied and then removed. This is shown in Fig. 5. Although the analogy of a powder under compression to a spring undergoing elongation is not exact, it does provide useful comparisons. The load is termed the stress and the change in length the strain.

Initially there is a rectilinear relationship between stress and strain, and if the stress is removed, the spring returns to its original length. This is elastic behavior and is completely reversible. The spring is said to obey Hooke's law and the reciprocal of the slope of this portion of the curve is Young's Modulus for the spring.

If the stress is further increased, eventually a point is reached when the straight-line relationship is lost. This is

Fig. 5 Stress-strain relationships.

termed the elastic limit. If stresses in excess of the elastic limit are applied and then removed, the spring will not return to its original length. Thus, a fraction of the change in length is permanent or irreversible, and this is termed plastic behavior. Further increase in load will result in more and more plastic deformation until eventually the load is so great that the breaking point of the spring is reached and it snaps. Now, consider now a number of particles constrained in the die of a tablet press and to which a progressively increasing force is applied. A series of events can then occur, perhaps sequentially but there is a greater likelihood that some overlap will occur.

The particles will undergo rearrangement to form a less porous structure. This will take place at very low forces, the particles sliding past each other. This stage will usually be associated with some fragmentation, as the rough surfaces move relatively to one another and asperities are abraded away.

The particles have now reached the stage where relative movement becomes impossible, although the porosity of the powder bed may still be considerable. A further increase in applied force can then induce elastic deformation, plastic deformation, or fragmentation. Which of these alternatives predominates will depend on the properties of the material involved, but the net result will be a further decrease in porosity, and an increase in interparticulate contact.

If only elastic deformation has occurred, then when the compressing force is removed, the particles will return to their former shape. The additional interparticulate contact caused by compression will be lost and a coherent tablet will not be formed Fig. 6.

If, however, the elastic limit has been passed, then as the force is removed, not all the increased interparticulate contact will be lost, cohesion will be retained and a tablet will be formed. Thus, from the point of view of forming a robust tablet, substances with low elastic limits, which undergo plastic deformation at low compressive forces, are preferable to more elastic bodies.

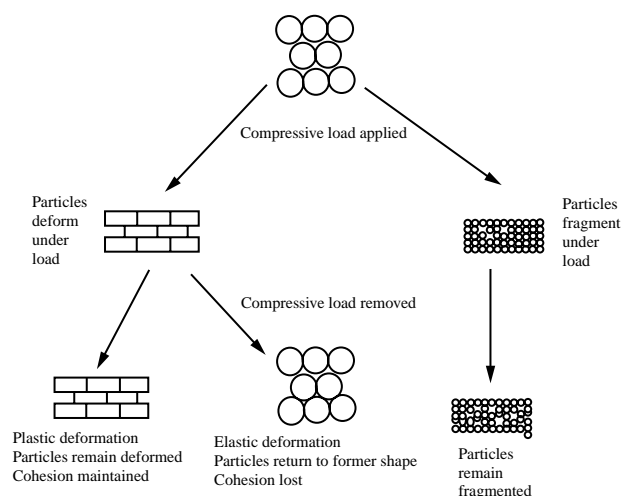

Fig. 6 Elasticity and plasticity in a particulate mass.

If consolidation of the powder mass is brought about by fragmentation, then a large number of points of interparticulate contact are created, from which the strength of the tablet derives. In this case, removal of the compressing force should have no effect on tablet strength, since there is no way the fragments can recombine into the original particles. However, purely fragmentary consolidation is unlikely to have occurred, and so the effect of removal of the force on deformed particles must still be considered.

Force Transmission through a Powder Bed

Consider as before a group of particles in the die of an excentric tablet press. Force is applied by means of the descending upper punch and because the lower punch is passive, the force will be transmitted to it through the powder bed. The distribution of force within the powder bed was investigated by Train, who embedded force transducers (q.v.) in a relatively large mass of powder (27). He found that the diminution of force did not proceed uniformly on descent through the bed, but formed a much more complex pattern. This was caused by the forces being transmitted to and reflected from the die wall. Significant features are zones of high force at the periphery near the moving punch, and much lower in the powder mass on its vertical axis. On the other hand, low force zones occur on the same axis but much nearer to the moving punch Fig. 7. Train's findings were later confirmed by Charlton and Newton using gamma-ray attenuation (28).

The consequences of such a force distribution on tablet strength can be profound. Particle deformation, whether elastic or plastic, will be proportional to the force applied,

Fig. 7 Density distribution in a compact prepared on an eccentric tablet press.

and as has been discussed, this deformation is an essential preliminary to the formation of the interparticulate bonds on which tablet integrity depends. Thus, the porosity of the tablet, and hence its strength, will vary within the tablet. The weakest points in the tablet structure will be those that receive the lowest force i.e., on the face of the tablet adjacent to the stationary punch and on the central axis near to the moving punch. Thus, because of its nonuniform density, some parts of a tablet are stronger than others.

It should be noted that this discussion assumes that only one punch is actively applying the force to the powder mass while the other is stationary and passive. This is true in the case of an eccentric press, but with a rotary tablet press, both punches move and hence both exert forces on the powder bed. The force distribution so obtained is thus different from that shown in Fig. 7, and results in two low density zones near the faces of the tablet and a high density zone in approximately the centre of the powder mass.

The effect of the removal of the compressing force must now be considered. Elastic recovery will occur to a greater or lesser extent, which will result in a reduction in the strength of interparticulate bonds and an overall weakening of the tablet. It therefore follows that if a tablet is to be disrupted by elastic recovery, this is most likely to occur at its weakest point. This is just below the top surface, and is the phenomenon often encountered in tablet manufacture known as lamination or capping. With this explanation in mind, some effects associated with capping, and some causes and pragmatic solutions to the problem can now be explained.

Capping was for many years considered to be due to the entrapment of air in the tablet, and even the production of tablets in vacuo which still capped did little to dispel this theory. Neither did this suggestion explain why air should cause the fracture just below the face of the tablet. However, by considering the nonuniform density distribution in the tablet, it can be seen that the weakness is not caused by the presence of air per se, but rather the relative absence of solid in those parts of the tablet that have high porosity (29). As compression proceeds, it follows that the pores in the tablet structure are filled with air at

a progressively elevated pressure, and this will obviously assist disruption of the tablet when the compressing force is removed. Thus, any factor which obstructs the expulsion of air from the powder mass during compression will exacerbate capping, though it is not the fundamental cause. Such factors include the clearance between punch and die, the speed at which the force is applied, and the presence of small particles, which makes passage of air through the tablet more tortuous (30).

Any applied stress that exceeds the breaking strength of the tablet will also cause the tablet to break at its weakest point. A number of stresses occur when the tablet is removed from the die after compression. The die may become worn at the point in the die where the tablet is compressed, i.e., the die is fractionally wider at this point than elsewhere. Thus, when the tablet is ejected, it is forced through an aperture, the diameter of which is slightly less than that of the tablet itself. This will obviously stress the tablet, and the interparticulate bonds may be overcome at their weakest point. Also as the tablet is extruded from the die, elastic expansion will occur not just in an axial but in a radial direction. The latter occurs progressively, i.e., one segment of tablet is free to expand while the one below is still constrained by the die. Bond disruption will be an inevitable consequence.

CHARACTERIZATION OF THE COMPACTION PROCESS

A range of parameters has been devised which attempts to describe the process of powder compaction, both to elucidate principles and also to enable predictions to be made regarding compaction properties. The majority of these depend on the availability of methods of accurately measuring applied force and punch position.

Measurement of Applied Force and Punch Movement

The aim of any tableting process is to produce tablets that are of satisfactory quality. Virtually all tablet properties e.g., porosity, physical strength, disintegration time, dissolution time are dependent in some way on the force that is applied by the punches to the particles in the die.

Considerable research on tablet properties was performed for many years, but until a method of accurately measuring compression force was available, meaningful studies could not be carried out.

The key to progress in this field was the introduction of the so-called instrumented tablet press by Higuchi and

others in the mid 1950s (31), in which force transducers were fitted to the press to measure the applied load. This revolutionized research into the tableting process and in addition has led to the development of presses with automatic tablet weight control, since the mass of particles in the die governs the force detected by the transducer (32) (see the article on Automation of Tablet Presses in this encyclopedia).

A force transducer is also known as a strain gauge. In its simplest form, the strain gauge is a network of wires through which an electric current is passed. The wires are bonded very securely to a component of the press, e.g., the upper punch. If a force is applied to the punch, it deforms. The magnitude of the deformation (the strain) is governed by a combination of the magnitude of the force (the stress) and the value of Young's modulus for the material from which the punch is made. The wire of the strain gauge is also deformed, and hence its electrical resistance changes. If the gauge is incorporated into a Wheatstone bridge circuit, then a small change in voltage results. The size of the signal from the strain gauge is proportional to the amount of deformation, which in turn is a function of the applied force. Hence, after amplification and appropriate calibration, the voltage changes can be expressed in terms of the applied force. Signals from the transducers can be fed into an oscilloscope or chart recorder, or stored electronically and subsequently manipulated by computer.

A further advance was the fitting of displacement transducers to tablet presses. These too give out an electrical signal, the magnitude of which is governed by the position of a sensing device in relation to a fixed reference point, and in this way punch movement can be measured. As before, these signals can be amplified, recorded, and stored. If the outputs of the force and displacement transducers are combined, the applied force at a given point in time, and punch position at the same instant can be established.

Instrumentation of rotary presses is more difficult than that for an excentric press if transducers are to be fitted directly to the punches. Since the turret of the press rotates, a fixed connection between transducers and the recording device is impracticable. Alternatives to fixed connections are slip rings and radiotelemetry. A further option is to fit transducers to points of the press remote from the punches and which do not rotate. Techniques for fitting transducers to both excentric and rotary tablet presses, their calibration, and applications of the information derived from instrumented presses have been reviewed by Watt (33).

Fig. 8 shows the output from force and displacement transducers fitted to both punches of an excentric tablet press. The upper punch describes an approximately sinusoidal path as it descends to penetrate the die (point

Fig. 8 Force and displacement data from an instrumented excentric tablet press.

A) and then rises after the compression event has taken place, leaving the die at point B. The lower punch remains motionless during the compression event and then rises to eject the tablet from the die (point C).

As the upper punch enters the die and comes into contact with the particles, the height of the bed of particles is reduced and hence porosity decreases. Initially porosity reduction is brought about by particle rearrangement. This requires a very low force which is probably not detectable by the force transducers, the output of which remains zero. The upper punch then encounters a resistance to its motion (point D) as further consolidation by rearrangement becomes impossible. Hence, the output of the upper punch force transducer rises, slowly at first and then more rapidly. Particles are deformed and/or fragmented during this stage to form a coherent tablet. Force is transmitted to the lower punch, and a similar rise is detected by transducers there. As maximum upper punch penetration is achieved (point E), force maxima are detected on both punches (points F and G), that on the lower punch being less than that on the upper.

Once the maxima have occurred, the upper punch begins to rise, and the force detected on both punches falls. That on the upper punch returns to zero as contact is lost between the ascending punch and the top surface of the tablet (point H). That on the lower punch does not fall to zero until ejection is complete (point J). The greater the ejection force, the greater the need for a lubricant in the formulation.

The reason why the lower punch maximum force is less than that of the upper punch is because a fraction of the force applied by the upper punch is transmitted to the die wall, where it results in die wall friction. This is reduced

by the presence of a lubricant. Hence, the ratio between lower punch maximum force and upper punch maximum force, often called the R value, is used as the basis of comparison between lubricants (34). R has a maximum value of unity and lubricants based on stearates usually exhibit R values greater than 0.95.

The time that elapses from point D to point F is known as the consolidation time. This is the time interval when a force is detectable at the upper punch. The contact time is the period when the upper punch is in contact with the original particles or the tablet (point D to point H). The residence time is the period when a force is detected at the lower punch (point D to point J), which ends on tablet ejection.

Transducer output from a rotary tablet press differs in two aspects. Firstly, the lower punch plays an active role in the compression event and moves upwards as the upper punch moves downwards. The second difference is small but important. Because of the sinusoidal movement of the upper punch in an excentric press, the punch speed is only zero at the instant when it reverses direction (point E). Punches on a rotary press have a flat area on the punch head. As the punches pass under or over the pressure rolls, the flat area dictates that there is no punch movement. The period during which this occurs is called the dwell time, and though it only lasts a fraction of a second, it can have a major effect on the consolidation process (35, 36).

Tablet Strength Profiles

The physical strength of a tablet is dependent on the extent and strength of interparticulate bonds and these in turn are related to the compressive force which is applied. Therefore, the relationship between the applied force and some parameter related to tablet strength is a good indication of the ease with which a given substance will form satisfactory tablets, and may also give an insight into the compaction mechanism of the solid and its mechanical properties.

The strength is usually assessed as the force required to fracture a tablet in a defined direction e.g., its diameter. This has traditionally been referred to as the "hardness" of the tablet, which is incorrect terminology in this context. In material science, hardness is a surface property related to resistance to indentation. Terms such as physical strength or mechanical strength are more appropriate.

The compression force is measured using an instrumented tablet press as described earlier. The physical strength of the tablet is measured with crushing apparatus such as that described in most current pharmacopoeias. The results are conventionally presented graphically with compression force as the abscissa and strength as the ordinate.

This technique is satisfactory when comparing tablets of the same size and shape, such as in-process control. However, if virtually identical tablets are not being tested, problems may arise. The force is sometimes expressed as the compression pressure, obtained by dividing the force by the cross-sectional area of the punch. This is valid if the punch has a flat surface, the area of which can be easily calculated; but in practice this is often not the case, and conversion between compression force and compression pressure involves assumptions regarding the area of the punch face, which may not be valid.

The physical strength of a tablet is also dependent on its dimensions. In the construction of a force-strength profile, all tablets will have the same cross-sectional area as the same tooling will have been used. However, as the compressive force is changed, so will the tablet height. Hence, comparisons made on the basis of breaking strength will not be truly valid.

This problem has been circumvented in part by the calculation of the tensile strength of the tablet. The most commonly used formula is shown in Eq. 1, introduced by Rudnick et al. (37) and Fell and Newton (38).

$$T_s = 2P/\pi dt \quad (1)$$

where T_s is the tensile strength of the tablet (MPa), P the crushing strength (N), d the tablet diameter (m), and t the tablet thickness (m).

This equation applies to cylindrical tablets which have a diameter and whose height is constant over the whole tablet surface. Newton et al. have attempted to extend the concept of tensile strength to tablets that are not cylindrical (39).

Confusion can often arise in the units that are used to express compression force or pressure and the strength of the tablet. Table 7 gives examples of units that have been used recently for the axes of tablet strength profiles. Comparison between different tablet formulations would be greatly facilitated if authors used and journal editors insisted on the use of the SI system of units. The SI unit of length is the meter, that of force the Newton and that of pressure the Pascal. The unit for physical strength is the Newton and that of tensile strength calculated from Eq. 1 is the Pascal.

Relationships between Tablet Porosity and Compression Force or Pressure

Fig. 8 shows the movement of both the upper and lower punches of the tablet press in relation to fixed reference points and from these data, the distance separating the two

Table 7 Some units used for the construction of tablet strength profiles

Abscissa parameter	Unit	Ordinate parameter	Unit
Force	kg	Crushing strength (hardness)	kg
	lb		Strong-Cobb units
	kN		N
	N		kp
Pressure	Kg cm ⁻²	Tensile strength	Kg cm ⁻²
	Pa		Pa
	MPa		MPa
	lbin ⁻²		

punch faces can be calculated. If both punch faces are in contact with the tablet, it follows that the distance of their separation is equal to the height of the tablet (h). Consequently, if the cross-sectional area of the die (a), the tablet weight (w) and the true density of the solid from which the tablet is made (ρ) are all known, the porosity of the tablet (ϵ) can be calculated from Eq. 2.

$$\epsilon = 1 - (w/ah\rho) \quad (2)$$

For cylindrical tablets, Eq. 2 becomes Eq. 3

$$\epsilon = 1 - (4w/\pi d^2 h \rho) \quad (3)$$

As the applied force (or pressure) being applied at the same moment in time can also be determined from Fig. 8, it follows that a relationship between force and porosity can be constructed.

A typical relationship is shown in Fig. 9. As force is increased from zero, the porosity of the tablet falls rapidly, but then further increase in force has a progressively smaller effect. The porosity value at which the curve becomes virtually horizontal is dependent on the solid being compressed. Substances that deform plastically typically give tablets of lower porosity than those which fragment.

Many equations have been derived in attempts to provide a mathematical expression of Fig. 9. These have been reviewed by Kawakita and Ludde (40). It must be stressed that such equations are simply mathematical descriptions of the data, and they have no underlying physical significance.

The most widely used of these equations is the Heckel relationship (41):

$$\ln 1/(1 - D) = kP + A$$

where D is the relative density of the tablet and hence $(1 - D)$ is the porosity, P is the applied pressure, and k and A are constants.

This equation predicts that a graph of $\ln 1/(1 - D)$ against P should yield a straight line of slope k and intercept A . Heckel surmised that the greater the slope, the greater degree of plasticity in the solid being compressed. Hersey and Rees (42) defined the reciprocal of k to be the mean yield pressure of the solid.

Fig. 10 shows a typical Heckel diagram. Deviations from linearity often occur at low and high pressures. These are to be expected. At low pressures, reduction in porosity is largely by particle rearrangement, and thus the true consolidation mechanism, i.e., fragmentation or deformation, will be a minor component of the total consolidation process. At high pressures, porosity can become very low and hence its reciprocal becomes a very large number.

However, the real problem with Heckel plots is identifying a truly rectilinear section. When pressure–porosity diagrams were first devised, instrumented tablet presses were not widely available. The height of the tablet was measured after ejection from the die and thus the net

**Fig. 9** A force–porosity diagram.

Fig. 10 Pressure and porosity data plotted according to the Heckel equation.

change in height was a combination of height reduction by consolidation and a height increase by elastic expansion. Furthermore, the typical plot comprised only a small number of points, and an apparently rectilinear zone could be identified. With improvements in instrumentation and in particular linkage to a computer, Heckel plots of several hundred points became feasible with tablet height measurements being made before ejection from the die. In the author's experience, the more points there are on a pressure–porosity diagram, the more difficult it is to identify a truly rectilinear section.

Paronen and Ilkka have surveyed the use of the Heckel and other compression equations and have drawn attention to difficulties in their interpretation (43).

Fig. 11 A force-displacement curve.

Force-Displacement Curves

Fig. 8 shows how force and punch displacement change with time. It is therefore possible to determine both the force and displacement values at any given point in time, and from this, a force–displacement curve can be constructed. Usually the force is plotted as the ordinate and displacement as the abscissa Fig. 11.

The area enclosed by the curve has the units of force (Newtons) multiplied by distance (metres), which is dimensionally equivalent to work or energy (in Joules). Therefore, the force–displacement curve has been used to calculate the work consumed in the compression of a solid (44).

Further refinement of this technique has enabled estimates of elasticity and plasticity of the solid to be made. If the particles were totally nonelastic, then as soon as the upper punch reached its maximum penetration and began to rise again, contact would be lost with the tablet. Therefore, the force recorded by transducers fitted to the upper punch would instantly fall to zero. This clearly does not happen, as demonstrated by the upper punch force values after maximum punch penetration in Fig. 8. This can only mean that as the upper punch ascends, the tablet expands elastically, keeping in contact with the punch face. Thus, the area ABC in Fig. 11 represents the work expended on compressing the solid, and area DBC is the work delivered back to the upper punch by the expanding tablet. The difference between these two areas (i.e., ABD) has been termed the “Net work” of compression.

Use of this technique has shown that the presence of a granulating agent causes a marked increase in the plasticity of the powder mass, with a consequent increase in cohesion and tablet strength. The film of granulating agent between the particles can be regarded as a highly viscous liquid with a large yield value. Application of a force in excess of the yield value causes granules to deform, and this becomes permanent when the force is reduced to below the yield value (45). A somewhat similar mechanism is believed to account for the properties of some direct-compression tablet diluents, e.g., spray-dried lactose, which consists of small crystalline masses embedded in an amorphous and more easily deformed matrix.

The force–displacement curve has been extensively used to characterize the compression event. However, it depends on the availability of sensitive and properly calibrated transducers. Even small inaccuracies in measuring displacement at high force values can have a profound effect on the resultant value of the area under the curve. Ragnarsson has provided a very thorough review of the uses and potential pitfalls of the force–displacement curve (46).

Time-Dependent Effects

It has long been known that for some formulations, changing the speed of operation of the tablet press or changing the type of press can have a profound effect on tablet quality. Such circumstances may arise, for example, when changing from a slow excentric press in formulation development to a high speed rotary in production.

As described earlier, diagrams of transducer output against time enable parameters such as contact time and dwell time to be defined Fig. 8. Also the slope of the displacement–time diagram equals the speed of the punch and the slope of the force–time diagram is the rate of change of the force. If the operating speed of the press is altered, there is a proportional change in all of these.

Such considerations are important because the consolidation of many substances is time-dependent. Fragmentation can be regarded as a virtually instantaneous process. However, substances that undergo deformation behave in a viscoelastic manner, and the time over which the compression force is applied can be crucial. As the time over which they are compressed is reduced, such materials show less consolidation and this in turn can affect the physical strength of the tablet. For example, Armstrong and Palfrey (47) studied the effects of punch speed change on the tablet strength of four direct compression diluents. Though tablet strength was reduced in all cases, solids such as modified starch suffered the greatest reduction. Roberts and Rowe investigated the relative sensitivity of the yield pressures of a range of solids to changes in compression speed, and again found that those solids which deformed on compression showed the greatest change (48).

The rate of consolidation in an excentric press is governed by the speed at which the upper punch moves into the die. This in turn is governed by the lengths of the excentric arms of the press and its speed of operation. In a rotary press, punch speed is governed by the diameter of the die table, the diameter of the pressure roll, the geometry of the punch head, and the speed of operation. Formulae for the calculation of punch speeds at any point of the compression cycle for both types of press have been derived (49, 50).

It is important to distinguish the punch speed from the output of the press. Though rotary presses have a much higher output than excentric presses, this largely derives from their multiplicity of punch stations. It does not necessarily follow that their punch speeds during compaction are significantly greater (51).

If the work of compression in Joules is divided by the time in seconds over which compression occurs, then the power of compression (in Watts) is obtained.

An alternative method of calculating power of compression is to multiply the force by the punch speed when that force was applied. This too can be obtained from the data in Fig. 8. This permits the compression events on different presses to be compared (49).

Tablet Manufacture by Direct Compression

Norman Anthony Armstrong

Welsh School of Pharmacy, Cardiff University, Cardiff, U.K.

INTRODUCTION

All tablets are made by compressing a particulate solid between two punches in a die of a tablet press. For an active ingredient to be transformed into tablets of satisfactory quality, the formulation must have three essential attributes.

First, the formulation must flow into the die space of the tablet press sufficiently rapidly and in a reproducible manner. Otherwise, unacceptable variation in tablet weight and content of active ingredient will ensue.

Second, the particles in the formulation must cohere when subject to a compressing force, and that coherence should remain after the compressive force has been removed.

Third, after the compression event is complete, it must be possible for the tablet to be removed from the press without damage to either the tablet or the press.

Very few active ingredients possess all three of these essentials and some possess none of them. Hence some preliminary treatment is almost invariably necessary.

METHODS OF TABLET MANUFACTURES

There are three methods of tablet manufacture designed to confer these essential attributes to a tablet formulation. Wet granulation and direct compression are the most important, with dry granulation (also known as precompression or slugging) used in some circumstances. Fig. 1 shows the processes of wet granulation and direct compression broken down into their constituent stages.

The relative simplicity of the direct compression process is immediately apparent.

Ease of removal of the tablet from the press is, in theory at least, readily achieved. Friction occurs between the tablet and the die and punches of the press, which can be overcome by including a lubricant in the formulation. Hence every formulation, irrespective of the method of manufacture, will include a lubricant. This will usually be a metallic salt of a fatty acid such as magnesium stearate.

The other two prerequisites—flow and cohesion—can only be achieved by more elaborate techniques and are in

fact the reasons why the wet and dry granulation processes were devised.

As part of its complexity, wet granulation involves the addition of a liquid (usually water), followed by its removal, normally by evaporation. In addition to the energy requirements of this drying process, the presence of water might bring about hydrolysis of the active ingredient, which will be exacerbated at the elevated temperatures used for drying.

If a major component of the formulation such as the diluent were to possess the necessary degrees of fluidity and compressibility, granulation would be unnecessary. This is the basis of the direct compression method of tablet manufacture.

Prior to the early 1960s, there were very few materials which possessed these properties. Little and Mitchell^[1] in their text *Tablet Making*, cite sodium chloride and bromide, potassium chlorate, bicarbonate and iodide, ammonium chloride, and hexamine as having properties which permit tableting without some form of prior treatment. No reference is made by name to the process of direct compression.

At about the same time, two materials were introduced that were specifically designed to act as tablet diluents and would not require preliminary treatment. These were spray-dried lactose and microcrystalline cellulose, introduced in 1962 and 1964, respectively. These two substances can be said to have initiated the “direct compression revolution.” Since that time, a wide range of direct compression tablet diluents has become available. The properties of some of these materials will be reviewed later in this article.

It is important to distinguish between true direct compression diluents (i.e., excipients) and active ingredients which are available in a direct compression form. These are usually high dose materials such as aspirin, paracetamol, and ascorbic acid. They can be directly compressed into tablets, the only pretreatment being mixing with a lubricant and perhaps a disintegrating agent. However, such substances are more accurately described as “pregranulated” since the granulation process, either wet or dry, will have been carried out by the excipient manufacturer. It is likely that such materials will contain a

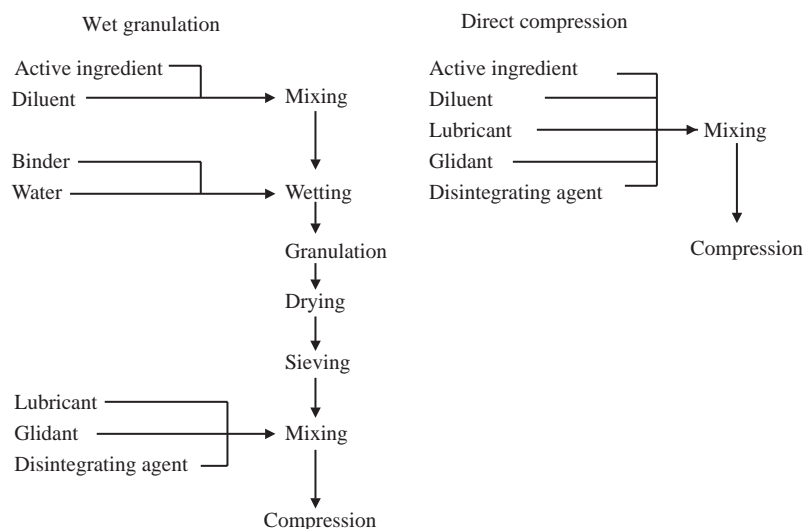

Fig. 1 Comparison of the wet granulation and direct compression processes of tablet manufacture.

binder. For example, ascorbic acid pregranulated with either starch or hydroxypropyl cellulose is commercially available.^[2]

The perceived advantages of the direct compression process of tablet manufacture have given rise to a considerable body of literature. Between 1970 and the end of 2000, there were 598 references to “direct compression” in the index of *International Pharmaceutical Abstracts*. It has been estimated that today, some 40 years after the introduction of diluents specifically designed for direct compression, about 50% of worldwide tablet production is made by this method.^[2] The question must be asked why a process which has so many apparent advantages and for which suitable materials seem to be plentifully available has not made a greater impact. An innate conservatism in the pharmaceutical industry is perhaps a factor, but cannot be the complete answer. It is interesting to consider as an analogy that the process of film coating of tablets, coincidentally introduced at about the same time as direct compression, has practically totally replaced the sugar-coating technique. This shows that a new process can achieve significant and relatively speedy penetration into an industrial environment if it represents a major step forward.

Wet Granulation Process: Advantages and Disadvantages

The wet granulation process is the traditional method of manufacture and is frequently used in the pharmaceutical industry. Expertise in wet granulation is widely available, as is the required equipment. The process improves flow

and cohesion, reduces dust and cross-contamination, and permits the handling of powder blends without loss of homogeneity.

Though it has been practiced for many years and therefore may be perceived as an “old-fashioned” process, it must be borne in mind that the wet granulation process has itself undergone a transformation in recent decades. High-speed mixer–granulators, fluidized bed granulation and drying, and an ever-increasing use of automation have served to make wet granulation a much more efficient and economic process than it once was.^[3]

Nevertheless, the wet granulation process still retains many inherent disadvantages. Problems include choice and method of addition of the binder, and the effect of drying time and temperature on drug stability and its distribution within the solid mass.

Direct Compression Process: Advantages and Disadvantages

The most striking feature of the direct compression process is its simplicity and hence economy. Less equipment is required and the number of stages in the process, each of which will require validation, is greatly reduced. There are also lower labor costs, reduced processing time, and lower power consumption.

An important advantage of the direct compression process is that it is a dry procedure with no need for a drying stage. Thus, exposure to water and the elevated temperatures needed to remove that water are avoided, resulting in a decreased risk of deterioration of the active ingredient.

A further advantage of direct compression is that tablets disintegrate into their primary particles rather than granular aggregates. The resultant increase in surface area available for dissolution should result in faster drug release.

The primary limitation on the use of direct compression is that it depends on the fluidity and compressibility of a tablet diluent. Therefore, it cannot be used for low potency, high dose active ingredients where the inclusion of sufficient diluent in the formulation to permit direct compression would lead to unacceptably large tablets. Thus, active ingredients such as paracetamol and aspirin do not lend themselves to the direct compression process. However, as stated earlier, such ingredients are often available in pregranulated form.

Paradoxically, one of the root causes of difficulties in the direct compression process is its simplicity. It must be regarded as a process in its own right, albeit a simple one, rather than a simplified form of the wet granulation process. The key point to grasp is that wet granulation produces what is in effect a new raw material, i.e., the granule. Minor variations in the properties of the constituents of that granule are covered up by “submerging” them in a mass of binder. This is not so with direct compression. The properties of each particle of every constituent remain essentially unchanged. There is thus a greater need for within-batch and between-batch consistency.

There is also the possibility of segregation of the constituents of the formulation after a homogeneous blend of active ingredient and excipients has been achieved. In a wet granulated product, particles are stuck together by the binder and so there is a much reduced chance of segregation. Because segregation is principally a function of differences in particle size between active ingredients and excipients, it is desirable that the size of the direct compression diluent matches that of the drug. This may not always be feasible.

The simplicity of the direct compression process should obviously bring financial benefits. However, it must be borne in mind that direct compression tablet diluents are considerably more expensive than conventional diluents such as α -lactose monohydrate.

Regulatory considerations also play a part in a decision whether or not to use the direct compression process. Several years may elapse between the finalizing of a tablet formulation and its marketing. During this period, stability testing of the product will have occurred. The formulator must be confident that a chosen direct compression diluent will still be available for a considerable time after product marketing; otherwise reformulation with all its attendant delay and expense will be required. A number of direct

compression diluents have been marketed that were withdrawn after only a few years because of lack of market penetration.

Progression of product development will be accompanied by scale-up of the manufacturing process of the active ingredient to commercial proportions. This may bring about changes in the physical properties of the active ingredient. As stated earlier, the wet granulation process can mask minor changes in physical properties, but this masking cannot occur in direct compression.

For these reasons, direct compression has been most widely adopted by manufacturers of generic (i.e., noninnovative) pharmaceuticals. During the time when the active ingredient is covered by patent protection, its optimum manufacturing process will have been achieved, and so subsequent batch-to-batch variation in its physical properties ought then to be minimal.

FACTORS INFLUENCING THE CHOICE OF A DIRECT COMPRESSION TABLET DILUENT

A wide range of substances is or has been marketed as direct compression tablet diluents. In general, these are commonly occurring materials whose properties have been modified in such a way to give the fluidity and compressibility demanded by the direct compression process. Many direct compression diluents are aggregates of primary particles. For example, an aqueous slurry of α -lactose monohydrate is spray-dried to give an agglomerated product that flows better and is more compressible than the parent substance. A second example is the acid hydrolysis of α -wood cellulose to yield particles containing bundles of microcrystals of cellulose. These can cohere by means of hydrogen bonds to give extremely strong tablets of microcrystalline cellulose.

Most direct compression diluents are available from only one source, but a few can be obtained from more than one manufacturer. If multiple sources are available, they will be offered under individual registered names. For example, microcrystalline cellulose is available under a number of brand names such as Avicel[®] (FMC Corporation), Emcocel[®] (Edward Mendell), and Viva-cel[®] (J. Rettenmaier). Chemical properties of such materials will be similar if not completely identical, especially if there are pharmacopeial standards for identity and purity. However, it cannot be assumed that products from different manufacturers will have the similar physical properties which will govern their performance in the tableting process.

Each brand will probably be accompanied by promotional literature to assist the sale of the product.

It is customary to describe its properties adjectivally, e.g., “excellent flow,” “superior compressibility,” and to present data referring to that material alone. Hence comparison between different excipients can be sometimes extremely difficult.

Several authors have listed the attributes of the “ideal” direct compression diluent.^[2,4] However, it must always be borne in mind that the diluent will invariably form part of a multicomponent mixture. At the very least, the diluent will be mixed with the active ingredient, and almost invariably a lubricant will also be present. The greater the proportion of active ingredient in the formulation, the less influence the diluent will have on the properties of the tablet.

One of the difficulties that beset the product developer is the lack of meaningful tests by which excipients (including direct compression diluents) can be assessed. This has led to the development of the so-called “functionality tests.” Some functionality tests that have been suggested (e.g., particle size, surface area) are in fact physical test methods being carried out under closely defined conditions.^[5] The relation of such a test to the actual function of the excipient needs to be established. After this link has been made, a more suitable title for these tests might be “functionality-related tests”.^[6]

Nevertheless, it is useful to consider some of the desirable properties of a direct compression diluent and how these properties can be appropriately measured.

Properties Required of a Direct Compression Diluent

Fluidity

Good flow is a prerequisite for any tablet formulation to ensure uniformity of tablet weight, which in turn contributes to uniformity of content. Flow can be measured by methods such as angle of repose, flow through an orifice, and by using flow cells, but more meaningful data can be obtained by measuring the uniformity of weight of the tablets themselves. Flow properties can often be improved by the inclusion of a glidant in the formulation.

Ease of mixing and lack of segregation

Achievement of a homogeneous mixture of active ingredient and diluent is essential to obtain tablets with an acceptable uniformity of content of active ingredient. As stated earlier, there is a risk of segregation in a direct compression mixture, because the components are not stuck together as they are in wet granulation. The main

cause of segregation is differences in the particle size of components, with differences in shape and density being secondary factors.^[7] Hence it is desirable that there should not be differences between the particle sizes of active ingredient and diluent. It is unlikely that the size of the active ingredient particles can be changed to match those of the diluent, so the reverse is desirable. Thus, the ideal direct compression diluent should be available in a range of sizes.

An alternative approach is to use the concept of ordered mixing in which fine particles of the active ingredient are dispersed over the surface of much larger diluent particles.^[8] This is only feasible with potent drugs when the diluent will comprise by far the major component of the formulation.

Compression pressure–Tablet strength profile

This is the relationship between the compression pressure applied to the formulation and the physical strength of the resulting tablets. It would seem to be a most important piece of information, yet its derivation is by no means straightforward. Also comparison of data derived by different researchers is often difficult.

If such data are presented graphically, either force or pressure can be used as the abscissa. Unless the cross-sectional dimensions of the tablet are known, interconversion between force and pressure is impossible. Furthermore, a wide variety of units of force and pressure have been used (Table 1), which again makes comparisons difficult if not impossible.

The physical strength of the tablet usually forms the ordinate of a graph. The variety of units used for this is also shown in Table 1. Here too interconversion can be

Table 1 Some units used for the construction of tablet strength profiles

Abcissa		Ordinate	
Parameter	Unit	Parameter	Unit
Force	kg	Crushing strength (hardness)	kg
	lb		Strong-Cobb units
	kN		N
	N		kp
Pressure	kg cm ⁻²	Tensile strength	kg cm ⁻²
	Pa		Pa
	Mpa		MPa
	lb in. ⁻²		

(From Ref. 9.)

extremely difficult. The breaking strength of a tablet is dependent on its physical dimensions. It is therefore logical to use some measure of strength that is independent of tablet size. Therefore the tensile strength of the tablet is often calculated according to Eq. 1.^[10]

$$T_s = 2P/\Pi dt \quad (1)$$

where T_s is the tensile strength of the tablet (MPa), P is the crushing strength (N), d is the tablet diameter (m), and t is the tablet thickness (m).

Use of this equation presupposes that the tablet is circular in cross-section and of uniform thickness, i.e., it is cylindrical. Pitt et al. have attempted to extend the concept of tensile strength to tablets which are not cylindrical.^[11]

Even though comparison is often difficult, it would be rendered considerably easier if the units used conformed to the SI system of weights and measures. Thus, the meter, newton, and pascal should be used as the units of length, force, and pressure, respectively.

Capacity or dilution potential

By definition, direct compression diluents are intended to be mixed with other ingredients. Therefore, not only should the pressure–tablet strength profile of the diluent be determined, but also should those of mixtures of the diluent with an active ingredient. The capacity of a direct compression diluent is the proportion of another ingredient that can be mixed with it while still obtaining tablets of acceptable quality. The definition of “acceptable” will depend on the purpose for which the tablets are required.

The magnitude of the effect that a given active ingredient will have on tablet properties will clearly depend on the tableting properties of that substance. If it is also capable of direct compression, then the effect will not be great. If, however, it is a substance that is difficult to compress into tablets, then it will cause a marked deterioration in tablet quality when mixed with the diluent. Therefore, for a reliable test of capacity, the direct compression diluent should be mixed with a “standard” substance and tableted under standardized conditions. The pressure–strength profiles of the mixtures can then be constructed. Paracetamol^[12,13] and ascorbic acid^[9] have been used as standards.

A method of quantitatively assessing the capacity of a direct compression diluent has been devised by Minchom and Armstrong^[12] who adapted a concept originally introduced by Malkowska and Khan.^[14] Tablets containing only diluent were prepared over a range of compression pressures, their strengths were measured, and a pressure–strength profile was constructed. A mixture of diluent plus

Fig. 2 Calculation of the capacity of a direct compression diluent. (From Ref. 9.)

active ingredient was then compressed under identical conditions, tablet strengths were determined, and the profile was constructed as before (Fig. 2).

The profiles were then fitted by regression analysis to quadratic equations, and integration of these equations between limits (in this case pressures of 100 and 300 MPa) gave the area under the curves. Thus, the change in tablet strength brought about by the addition of the active ingredient is given by the ratio $B/(A + B)$. Details of the application of this method to mixtures of direct compression lactose and ascorbic acid are shown in Table 2.^[9] The technique has been developed further by Habib et al.^[15]

The effect of the active ingredient on flow properties can be determined at the same time by calculating the uniformity of weight of the tablets used to prepare pressure–strength profiles.

Reworking

A faulty batch of tablets can sometimes be recovered by grinding up the tablets and recompressing them, a process

Table 2 Areas under pressure–tablet strength profiles for mixtures of ascorbic acid and direct compression lactitol

Ascorbic acid concentration (%)	Area ratio
0	1.00
20.0	0.75
33.3	0.47
42.9	0.35
50.0	0.32
55.8	0.27
60.0	0.20

(From Ref. 9.)

which is known as reworking and is analogous to the dry granulation method of tablet manufacture. This can sometimes cause problems with a direct compression formulation. Many direct compression diluent particles are in the form of aggregates, e.g., spray-dried lactose is composed of small crystals of lactose embedded in amorphous lactose. If these aggregates are compressed, their structure may be broken down to such an extent that subsequent recompression will result in impaired tablet quality.

The technique of Malkowska and Khan,^[14] used as described before to determine the capacity of a direct compression diluent, was originally developed as a method of expressing the ability of a formulation to be reworked. Referring to Fig. 2, the upper curve represents the strength of tablets prepared without reworking and the lower curve is the strength of reworked tablets. The reworking index is calculated from the ratio of the areas under the curves as described previously.

The mechanism of consolidation

A fundamental property of a solid is the mechanism by which it consolidates under the influence of a compressing force. There are two principal mechanisms—fragmentation and deformation—though most solids will show a mixture of the two with one mechanism predominating. The mechanism can have a major influence on tablet properties.

The effect of compression speed on tablet quality is dependent on the consolidation mechanism. Fragmentation can be regarded as a virtually instantaneous process. Thus, solids which consolidate by fragmentation show little dependence, if any, on the speed at which the consolidation pressure is applied. Deformation on the other hand is time-dependent. It takes a finite time for deformation to occur, and at high rates of punch movement, not enough time may be available for the full effect of the pressure to be exerted.

Table 3 Strain rate sensitivities of powders

Substance	Strain rate sensitivity (%)
Calcium phosphate	0
Calcium carbonate	0
Heavy magnesium carbonate	0
Paracetamol DC	1.8
Paracetamol	10.6
Lactose	16.2
Tabletose	19.2
Anhydrous lactose	20.3
Avicel PH101	38.9
Sodium chloride	39.9
Mannitol	46.4
Maize starch	49.3

(From Ref. 17.)

Changes in punch speed can arise by changing the speed of the tablet press or by changing from a relatively slow-speed excentric press to a high-speed rotary. It must be stressed that the key parameter is punch speed rather than production rate.^[16] Roberts and Rowe^[17] derived a parameter that they called the strain rate sensitivity. This classifies substances according to how tablet strength is affected by changes in punch speed. Details of some of the substances investigated by Roberts and Rowe are shown in Table 3, and many of these are direct compression diluents.

The practical implications of this work are shown in Table 4.^[18] As punch speed is increased, the strength of tablets of dicalcium phosphate is only marginally affected, whereas those made of starch suffer a severe reduction in their strength. As punch speed is increased, speed-sensitive materials give a progressively more porous and hence weaker tablet. It follows that in any report on the tableting properties of a diluent, the type of press and its speed of operation should be stated.

A second area in which consolidation mechanism is important is in the sensitivity of diluents to the effects of

Table 4 Tablet tensile strengths (MPa) produced by a compression pressure of 80 MPa on an excentric press

Press speed (tablets per minute)	Dicalcium phosphate	Lactose	Microcrystalline cellulose	Starch 1500
20	0.63	0.77	5.4	0.28
40	0.62	0.76	5.2	0.25
160	0.60	0.68	3.9	0.15
% reduction	5.0	12	28	47

(From Ref. 18.)

lubricants. In general, addition of a lubricant such as magnesium stearate causes a reduction in tablet breaking strength. As the diluent is mixed with the lubricant, each diluent particle becomes coated with a thin film of lubricant which interferes with interparticulate bonding. However, if fragmentation is the primary method of consolidation, new surface that is uncontaminated by lubricant is continually generated, and so bonding is less affected. Thus, factors which affect the distribution of the lubricant over the diluent surface may have an influence on tablet strength, the magnitude of which depends on the predominant consolidation mechanism. Such factors include mixer design and mixing time and speed.^[19] It follows that the lubricant, its concentration, and method of incorporation should be stated in any publication relating to direct compression diluents.

TABLET DILUENTS USED IN DIRECT COMPRESSION

A wide variety of materials have been used as direct compression diluents, and this has given rise to a considerable literature. Many research reports originate with organizations marketing a specific diluent, or are derived from work sponsored by that organization. Such publications will obviously report data and results relevant to that one diluent.

However, there are some publications which seek to compare a range of diluents, and these are particularly valuable.^[20,21] Perhaps, the most comprehensive review of direct compression diluents has been published by Bolhuis and Chowhan.^[2] Monographs of many direct compression diluents are to be found in the *Handbook of Pharmaceutical Excipients*, which contains details of the physical properties of these substances.^[22]

Direct compression diluents are often commonly occurring substances which have been physically modified to give the necessary degree of fluidity and compressibility. They are most conveniently classified according to their source, viz.:

- Cellulose and cellulose derivatives.
- Inorganic materials.
- Polyols.
- Starch and starch derivatives.
- Sugars.
- Mixtures and coprocessed products.

Information on some direct compression diluents is given in Table 5.

Cellulose and Cellulose Derivatives

Since its introduction as a direct compression diluent in 1964, microcrystalline cellulose has become a pharmaceutical excipient of great importance. It consists of aggregates of microcrystals and is isolated from α -wood cellulose by acid hydrolysis.

When compressed, microcrystalline cellulose particles deform plastically and the surfaces thus brought into contact unite by hydrogen bonding. Because tablets made from microcrystalline cellulose are extremely strong, there is a high dilution potential and they can withstand weakening caused by lubricants.^[19] In fact, microcrystalline cellulose tablets exhibit such a low coefficient of friction that they may need no lubricant. Fluidity of microcrystalline cellulose is low and the addition of a glidant may be necessary. Its bulk density is also low. Unlike many direct compression diluents, it is available in a wide range of particle sizes.

Microcrystalline cellulose is available from several different sources. These can exhibit a range of tableting properties, and so the substitution of one brand of microcrystalline cellulose by another must be approached with caution.^[23] Microcrystalline cellulose is quite hygroscopic, and its tableting properties are dependent on its moisture content, with water causing the interparticulate hydrogen bonds to weaken. Therefore, comparisons between different brands must also take the moisture content into account.^[24]

Powdered cellulose has been used as a direct compression diluent. Though it forms hard tablets, fluidity is poor and dilution potential is low. Like microcrystalline cellulose it has some self-lubricating properties, but addition of a lubricant is usually necessary, causing a marked reduction in tablet strength.^[25]

Silicified microcrystalline cellulose is a coprocessed mixture of microcrystalline cellulose and 2% colloidal silicon dioxide, which has improved flow and binding properties compared to microcrystalline cellulose itself.^[26]

Inorganic Materials

The most widely used inorganic direct compression diluent is calcium phosphate. It is available in several forms, but the unmilled (i.e., coarse) dibasic dihydrate ($\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$) is the most frequently used. It has good flow and binding properties. Consolidation is principally by fragmentation, so although a lubricant is needed, tablet strength loss is low.^[19] It is nonhygroscopic at humidities up to 80%, and due to its hydrophilic nature, dicalcium phosphate dihydrate tablets are rapidly penetrated by water on immersion. Despite this, the tablets

Table 5 Direct compression diluents, their proprietary names, and their manufacturers

Diluent	Proprietary name	Manufacturer
<i>Cellulose and cellulose derivatives</i>		
Cellulose, microcrystalline	Avicel [®]	FMC

Lactose–povidone	Ludipress [®]	BASF

do not disintegrate because they are almost insoluble in water.^[27] Dicalcium phosphate dihydrate is, however, soluble in acidic media such as gastric juice.

The water of hydration is relatively easily lost from dibasic calcium phosphate dihydrate, and this may have consequences for the stability of products containing it.^[28]

Anhydrous dibasic calcium phosphate and calcium triphosphate can also be used for direct compression. The latter is actually a mixture of calcium phosphates including tricalcium orthophosphate [$\text{Ca}_3(\text{PO}_4)_2$] and hydroxyapatite [$\text{Ca}_5(\text{OH})(\text{PO}_4)_3$]. The preparation and properties of calcium phosphates have been reviewed by Carstensen and Ertell,^[29] and their tableting properties have been studied by Bryan and McAllister.^[30]

A direct compression diluent based on calcium sulphate is also available.^[31]

Polyols

Several solid polyols can be used as direct compression diluents, usually after some physical modification. Most such polyols can be obtained from natural sources, but are usually manufactured by hydrogenation of the parent sugar molecule. Some properties of polyols, together with comparative data for lactose and sucrose, are shown in Table 6.

Sorbitol

This is probably the most commonly used polyol in tablet manufacture. It is freely soluble in water, producing strong tablets. Its negative heat of solution, which produces a cooling effect in the mouth, makes it particularly useful in chewable tablets and “sugar-free” confectionary. Furthermore, most polyols are noncariogenic, which increases their usefulness in this area. It is hygroscopic, and shows an appreciable increase in moisture content with attendant impairment of flow properties when exposed to relative

humidities in excess of 65%. At very high humidities, sorbitol absorbs enough water to bring about dissolution.

Sorbitol can exist in four crystalline forms. Guyot-Hermann et al.^[32] compared 11 commercially available varieties of sorbitol, and found three of these four forms to be present. γ -Sorbitol was found to be the most useful as a tablet diluent. The method of manufacture has also been shown to affect tableting properties, differences being attributed to variations in particle shape and surface properties. Spray-dried varieties of sorbitol are available as direct compression diluents which are claimed to have overcome problems associated with the different crystalline forms.^[33]

Mannitol

Mannitol is an isomer of sorbitol. Like the latter, it has a negative heat of solution which makes it a useful excipient for chewable tablets and lozenges. It is less hygroscopic than sorbitol and has about one-tenth of the solubility in water. Similarly to sorbitol, several polymorphic forms are available which differ in their ability to form tablets.^[34] However, unmodified mannitol cannot be used for direct compression because of poor flow and binding properties. Directly compressible forms are available in a range of particle sizes which are reported to produce excellent tablets.

Lactitol and xylitol

These are both commercially available in forms suitable for direct compression with good flow and binding properties. The former is a water-granulated product of microcrystalline aggregates.^[35] A similar form of xylitol is available, and in the case of xylitol, there are also products pregranulated with either polydextrose or carboxymethyl cellulose.^[36] Both substances are highly soluble in water with negative heats of solution.

Table 6 Properties of some polyols

	Solubility in water (g per 100 cm ³)	Melting point (°C)	Heat of solution (J g ⁻¹)	Water content at			Sweetness (sucrose = 100)
				55% RH	75% RH	100% RH	
Lactitol	170	180	-54	0.0	0.1	37.2	35
Mannitol	18	167	-121	0.5	0.5	83.7	50
Sorbitol	200	110	-113	6.4	10.4	122.2	60
Xylitol	160	94	-153	0.1	0.1	70.6	100
Lactose	22	201	-18	0.8	0.8	7.0	15
Sucrose	200	160	-17	1.0	1.0	38.0	100

Starch and Starch Derivatives

Starch is a very widely used tablet excipient, but in its natural state, it does not possess the fluidity and binding characteristics needed as a tablet diluent. The major consolidation mechanism of starch is by deformation with a high elastic component.^[37] In addition, starch shows a high degree of lubricant sensitivity.^[19]

Pregelatinized starch, often referred to as Starch 1500, contains about 80% unmodified starch, 5% free amylose, and 15% free amylopectin. Though it has been described as a direct compression diluent,^[38] tablets made from pregelatinized starch show low physical strength. The principal application of pregelatinized starch in tablet formulation is as a disintegrating agent. It retains the disintegrating ability of natural starch without the deleterious effects on flow and tablet strength that natural starch would bring about.

Sugars

Lactose

Lactose is a naturally occurring disaccharide containing one galactose unit and one dextrose unit. It is a constituent of all forms of mammalian milk, but is produced commercially from cow's milk, usually as a by-product of the cheese industry. Lactose can exist in two isomeric forms, α -lactose and β -lactose, and can be either crystalline or amorphous. Crystalline α -lactose occurs in both monohydrate and anhydrous forms, but β -lactose only exists in the anhydrous form. The temperature of crystallization is the principal determinant of which form is obtained.^[39]

Though crystalline α -lactose monohydrate is the most common tablet diluent, it is usually used in granulated rather than in direct compression formulations. Neither its flow properties nor its binding properties are good enough to form satisfactory tablets without preliminary treatment. Bonding properties are improved by conversion into aggregates of α -lactose monohydrate crystals by fluid bed granulation. This product is virtually free from amorphous lactose.^[40]

Spray-dried lactose was the first direct compression diluent to be introduced.^[41] It had a major impact on tableting technology and it is still widely used. Spray drying an aqueous suspension of lactose yields a product that largely consists of crystals of α -lactose monohydrate (about 80%) held together in a glass of amorphous material (about 20%). Spray-dried lactose exhibits excellent flow properties due to the spherical shape of the aggregates. However, its ability to form strong tablets is

limited and it has low dilution potential, so it is primarily used in tablets in which it forms the major ingredient. Fragmentation is the major consolidation mechanism, and so tablet strength is not significantly affected by lubricants. Spray-dried lactose can be obtained from several manufacturers whose products differ slightly. A comparative study of spray-dried lactoses from a number of sources has been published by Whiteman and Yarwood.^[21]

Anhydrous lactose is primarily anhydrous β -lactose with up to about 25% anhydrous α -lactose. It consists of agglomerates of fine crystals produced by roller drying a solution of α -lactose monohydrate. Flow properties are good, and tablet strength was found to be superior to other lactose products.^[21] Anhydrous β -lactose is much more soluble than the α -isomer, and extended disintegration times of tablets made from anhydrous lactose have been attributed to the presence of anhydrous α -lactose in the roller dried product.^[42]

Anhydrous α -lactose can be produced by thermal or chemical dehydration of α -lactose monohydrate. During this process, the starting material changes from single crystals to aggregates of anhydrous α -lactose particles. Flowability and binding properties are good, but slow dissolution of tablets made from anhydrous α -lactose has proved a major limitation to its use.^[42]

Sucrose

A nonreducing disaccharide obtained from vegetable sources, sucrose is a widely used pharmaceutical excipient. Because it is more hygroscopic than lactose, it is used less in solid dosage forms. The compactability of pure sucrose is poor, but modified forms of sucrose for direct compression are available. These are collectively termed "compressible sugar," and may contain, depending on source, starch, maltodextrin, or invert sugar, together with a lubricant. Several different types of compressible sugar have been compared.^[43] The minor components obviously played a major role in tablet formation, since significant differences were obtained between varieties. Compressible sugar is often used for lozenges and chewable tablets—because of the high solubility of sucrose, tablets tend to dissolve rather than disintegrate.

Dextrose and dextrates

Dextrose does not lend itself to direct compression. However, a spray-crystallized product, the major constituent of which is dextrose, is used in direct compression. This is known as dextrates, and is produced by the partial hydrolysis of starch. It consists of about 90% dextrose, together with about 5% maltose and higher polysaccharides.^[44]

Though both hydrated and anhydrous forms of dextrates have been described, only the former is commercially available. Dextrose is freely soluble in water and is highly hygroscopic, and hence its use in atmospheres of high humidity may cause problems. Because of its sweet taste and negative heat of solution, it is recommended for use in chewable tablets.

Mixtures and Coprocessed Products

Though numerous direct compression diluents are available, none is ideal. For example, spray-dried lactose flows easily but forms relatively weak tablets, whereas the fluidity of microcrystalline cellulose is poor yet it forms extremely strong tablets. It is understandable, therefore, that the possibilities of combining diluents have been considered, the aim being to combine the advantages of both components without their disadvantages.

The compaction properties of mixtures have been reviewed by Fell,^[45] who concluded that the relationship between the tableting properties of a mixture could only rarely be predicted from knowledge of the same properties of the individual components. Nevertheless, some success has been achieved.^[46]

In recent years, a number of coprocessed excipient combinations have been marketed, which undoubtedly possess advantages over physical mixtures of the same components. Such materials include mixtures of lactose and povidone,^[47] cellulose and lactose,^[48] and anhydrous lactose and anhydrous lactitol. A disadvantage of this approach is that the relative proportions of the components are fixed, and such a combination may not be universally optimal.

Tablet Press Instrumentation

Michael Levin

Metropolitan Computing Corporation, East Hanover, New Jersey, U.S.A.

INTRODUCTION

This article is designed to facilitate the understanding of the general principles of tablet press instrumentation and the benefits thereof by the formulators, process engineers, validation specialists, and quality assurance personnel, as well as production floor supervisors who would like to understand the basic standards and techniques of getting information about their tableting process.

HISTORY OF TABLET PRESS INSTRUMENTATION

In 1952–1954 Higuchi and his group^[1] have instrumented upper and lower compression, ejection, and punch displacement on an eccentric tablet press, and pioneered the modern study of compaction process. This work was followed by Nelson^[2,3] who was the member of the original group.

In 1966, a U.S. patent was granted to Knoechel and co-workers^[4] for force measurement on a tablet press. This patent was followed by two seminal articles in *Journal of Pharmaceutical Sciences* on the practical applications of instrumented rotary tablet machines.^[5,6] A number of other patents related to press instrumentation and control followed from 1973 on ward.^[7–15]

Despite the availability of published designs for instrumenting rotary presses, much of the early work on compaction properties of materials was done on instrumented single punch eccentric presses primarily, due to the relative ease of sensor installation, as well as availability of punch displacement measurement.^[16–18]

In mid-1980s, custom-made press monitoring systems were described,^[19,20] and the first commercial instrumentation packages became available, including both the systems for product development and press control. The first personal computer-based tablet press monitor was sold in 1987, and the first Microsoft Windows-based press instrumentation package in 1995.

A new era of compaction research has begun with the introduction of an instrumented compaction simulator^[21]

in 1976, while a compaction simulator patent was issued as recently as 1996.^[22]

A new generation of “compaction simulators” was born when a mechanical press replicator was patented in the year 2000.^[23]

A good exposé of the early stages of press instrumentation and resulting research is presented in review articles by Schwartz,^[24] Marshall,^[25] and Jones.^[26] A comprehensive review can be found in a relatively recent paper by Çelik and Ruegger.^[27]

For other historical information on the press instrumentation, the reader is encouraged to peruse Ridgeway Watt's^[28] volume. There have been a number of papers published on various disparate instrumentation topics, and in a recent volume by Muños-Ruiz and Vromans,^[29] there are two good articles on the subject—but, unfortunately, they deal with marginal issues of single station press and instrumented punch only.

DATA ACQUISITION PRINCIPLES: FROM TRANSDUCERS TO COMPUTERS

To monitor and control a tablet press, certain sensors must be installed at specific locations on the machine. These sensors are called transducers. In general, a transducer is a device that converts energy from one form to another (e.g., force to voltage). Tablet press transducers typically measure applied force, turret speed, or punch position. Because the signals coming from such transducers are normally in millivolts, they need to be amplified and then converted to digital form in order to be processed by a data acquisition system.

Piezoelectric Gages

Historically, high impedance piezoelectric transducers that employ quartz crystals were used in early stages of press instrumentation. When subject to stress, the crystal accumulates electrostatic charge that is directly proportional to the applied force. Both low and (more modern) high impedance piezoelectric gages have high-frequency response, but may exhibit signal drifting due to charge

leakage (approximately 0.04% decay per second can be seen in modern piezoelectric transducers). Nowadays, the preferred way of instrumenting tablet presses is with strain gages.

Strain Gages

Strain gages are foil, wire, or semiconductor devices that convert pressure or force into electrical voltage. When a stress is applied to a thin wire, it becomes longer and thinner. Both factors contribute to increased electrical resistance. If an electrical current is sent through this wire, it will be affected by the changes in the resistance of the conduit. This principle is used in strain gage-based transducers. Foil gages, known for robust application range, useful nominal resistance, and reliable sensitivity control, are most commonly used for instrumentation of compression, precompression, and ejection forces. Semiconductor-based strain gages are inherently more sensitive but suffer from high electrical noise and temperature sensitivity. Such gages are not commonly used in tablet press instrumentation except for measurement of die-wall pressure and take-off forces.

Wheatstone Bridge

Wheatstone bridge (Fig. 1) is a special arrangement of strain gages that is used to ensure signal balancing. The “full” bridge is composed of two pairs of resistors in a circle, with two parallel branches used for input and two for signal output. By applying the so-called excitation voltage (typically, 10 V DC) to the bridge input and changing the resistance of different “legs” of the bridge by adding special resistors, we can make sure that there is a zero output voltage when no load is applied to the transducer. This is called zero balance. Once the bridge is

Fig. 1 A typical Wheatstone bridge arrangement of strain gages.

balanced, a small perturbation in the resistance of any “leg” of the bridge results in a nonzero signal output.

The output of the Wheatstone bridge is normally expressed in millivolts per volt of excitation per unit of applied force. For example, sensitivity of 0.2 mV/V/kN means that applying, say, 10 kN force and 10 V excitation will produce 20 mV output. To utilize such output, it usually needs to be amplified several hundred times to reach units of volts.

Another important function of the bridge is balancing of temperature effects. Although individual strain gages are sensitive to temperature fluctuations, Wheatstone bridge arrangement provides for temperature sensitivity compensation, so that the resulting transducer is no longer changing its output to any significant degree when it heats up.

Because the output of these bridges is in the range of millivolts, the cables utilized to carry the signal are normally shielded with a braided or foil-lined sheath around individual wires. The shield, as a rule, is connected to the amplifier, but never touches the actual instrumented equipment (i.e., tablet press). If this rule is violated, a ground loop may generate electrical noise and present a dangerous electrical shock hazard.

Gage Factor

The gage factor is a specific characteristic of a strain gage. It is calculated as the change in resistance relative to unit strain that has caused this change. Strain gages that are commonly used for tablet press instrumentation are made from copper–nickel alloy and have a gage factor of about 2. In a typical bending beam application (such as compression roll transducer), one side of the beam experiences tension while the other side undergoes compression. By mounting two gages on each side, the sensitivity of the transducer can be doubled.

Strain gages have to be bonded to areas of machine parts that are most sensitive to applied force. Such areas can be identified with the use of polarized light technique that “points out” the stress distribution.

Manufacturing a Force Transducer

Usually, instrumentation designs are proprietary and specific detail drawings are held in fiducial capacity. Each force transducer is custom designed for a particular machine part. Overall specifications are taken from the actual party and/or manufacturer approved drawings.

Duplicate steel members, such as pins and cams, are normally made from A2 tool steel in a fully annealed

Tablet Press Instrumentation

(softened) state. Original machine parts are first annealed, if required. The member is then machined, hardened to Rockwell 60–64, tested, and finally, ground to specified dimensions.

It is highly advantageous to determine stress distribution using polarized light beams identifying the areas of maximum strain yet avoiding areas of uneven strain.

A typical procedure of transducer manufacturing in a professional gaging lab might be as follows. Foil type strain gages are bonded to the steel member utilizing a high-performance 100% solid epoxy system adhesive under controlled heating rate conditions. After intrabridge wiring is completed using solid conductor wiring (to prevent electrical noise), multistrand wire cabling with a combination of foil and braided insulation is connected to the bridge. Wire anchoring is achieved utilizing epoxy adhesive and protected with a combination of latex-based adhesives and/or epoxy resins. Lead wire cabling is protected by Teflon outer shield, as well as inner braided wire shield. The Teflon to steel joint is sealed with epoxy but should not be subject to stresses that would cause the cable to kink or yield in such a way as to expose the inner braided wire shield. Protective coatings are then applied and final postcure heating is performed for at least 2 hr at a temperature approximately 50°C above the transducer normal operating temperature (approximately 175 or 105 °C). A silicon-based adhesive, such as RTV, is used to fill large cavities while maintaining a low modulus of elasticity, preventing undue influence upon the actual strain measurement. The coating is resilient to moderate mechanical abrasion, as well as most solvents, oils, cleaners, etc. It is not intended for protection against penetrating sharp objects.

A high-quality connector is then attached to the cable. The next step is to perform offset zeroing with fixed, 1% precision, low-temperature coefficient resistors, followed by NIST (National Institute for Standards and Technology) traceable calibration.

It is worth noting that, in general, the duplicate members are not made of corrosion-resistant steel, because high tensile strength and ability to be easily machined are required. Prior to storage, the surface should be treated like any high-grade tablet press punch steel will be treated; a thin coating of oil should be used after wiping with alcohol.

Load Cells

In some cases, where appropriate, a load cell can be used in place of bonded strain gages.

A load cell is a strain gage bridge in an enclosure forming a complete transducer device.

Like any properly made transducer, it produces an output signal proportional to the applied load. Unlike custom-made transducers that require application of strain gages directly to press parts, load cells are self-contained and can be placed on a press in specially machined cavities to be easily replaced or serviced. As a drawback, load cells generally are less sensitive or less suited to measure the absolute force than custom-made strain gage transducers. Load cells can be used on punch holders in a single station press. Another example of load cell use is a die assembly for calibration of existing traducers on a press.

Linear Variable Differential Transformer

Linear variable differential transformer (LVDT, Fig. 2) is a device that produces voltage proportional to the position of a core rod inside a cylinder body. It measures displacement or a position of an object relative to some predefined zero location. On tablet presses, LVDTs are used to measure punch displacement and in-die thickness. They generally have very high precision and accuracy, but there are numerous practical concerns regarding improper mounting or maintenance of such transducers on tablet presses.

Proximity Switch

Proximity switch (Fig. 3) is a noncontact electromagnetic pickup device that senses the presence of metal. On tablet presses, it is widely used to detect the beginning of a turret

Fig. 2 Linear variable differential transformer (LVDT).

Fig. 3 Proximity switch.

revolution, to identify stations and to facilitate peak detection in tablet force control applications.

Instrumentation Amplifier and Signal Conditioning

Signal conditioning involves primarily an amplifier that provides the excitation voltage, as well as gain (a factor used in converting millivolt output of the strain gage bridge to the volt-based range of the input of the data acquisition device).

Instrumentation amplifier is different from other types of amplifiers in that the signal from each side of the transducer bridge is amplified separately and then the difference between the two amplified signals is, in turn, amplified. As a result, noise from both sides of the sensors is reduced.

Some instrumentation amplifiers also offer filter functionality. A filter circuit combines resistors and capacitors that act to block the undesirable frequencies. It is a fact, however, that a good transducer should provide a clean signal. Use of analog or digital filters may cause the loss of some important portions of the signal that one is attempting to measure. Frequency filters may cause the measured compression force peak, for example, to be skewed toward the trailing edge of the peak and can yield a lower than actual peak force.

Because filters distort the signal, they must be avoided unless absolutely necessary. In many cases, better electronics may make filter use obsolete. For example, the so-called antialiasing filter that is used to condition a high-frequency signal for a slow sampling rate is generally not required for tablet press applications if modern fast speed data acquisition devices are used for signal processing.

In addition to amplification, excitation, and filtering, signal-conditioning devices may provide isolation, voltage division, surge protection, and current-to-voltage conversion.

Instrumentation Terms: Definitions

Several important terms may be now defined with respect to transducers and signal conditioning:

- **Full Scale (FS):** The total interval over which a transducer is intended to operate. Also, it can define the output from transducer when the maximum load is applied.
- **Excitation:** The voltage applied to the input terminals of a strain gage bridge.
- **Accuracy:** The closeness with which a measurement approaches the true value of a variable being measured. It defines the error of reading. Good tablet press transducers have at least 1% accuracy (with this level of accuracy, for example, a compression force transducer with 50 kN FS will produce at most an error of 500 N).
- **Precision:** Reproducibility of a measurement, i.e., how much successive readings of the same fixed value of a variable differ from one another. If a person is shooting darts, for example, the accuracy is determined by how close to the bull's eye the darts have landed, while the precision will be indicated by how close the darts are to each other.
- **Resolution:** The smallest change in measured value that the instrument can detect.
- **Dynamic range of a transducer:** The difference between the maximal FS level and the lowest detectable signal. Measured in decibels (dB), it indicates the ratio of signal maximum to minimum levels:

$$\text{dB} = 10 \log_{10}(S_{\max}/S_{\min})$$

Some press sensors may have a rather narrow dynamic range not necessarily correlated with accuracy. For example, a very accurate compression roll pin designed to measure 50 kN force may not detect 5 kN signal.

- **Calibration:** Comparison of transducer outputs at standard test loads to output of a known standard at the same load levels. A line representing the best fit to data is called a calibration graph.
- **Calibration factor:** A load value in engineering units that a transducer will indicate for each volt of output, after amplifier gain and balance. Calibration factor is usually expressed in relation to FS.
- **Shunt calibration:** A procedure of transducer testing when a resistor with a known value is connected to one leg of the bridge. The output should correspond to the voltage specified in the calibration certificate. If it does not, something is wrong and the transducer needs to be inspected for possible damage or recalibrated.

- **Sensitivity:** The ratio of a change in measurement value to a change in measured variable. For example, if a person ate a 1 lb steak and the bathroom scale shows 2 lb increase in the body weight, then the scale can be called as insensitive (ratio is far from unity).
- **Traceability:** The step-by-step transfer process by which the transducer calibration can be related to primary standards. During any calibration process, transducer is compared to a known standard. National or international institutions usually prescribe the standards. In the United States, such governing body is the NIST.
- **Measurement errors:** Any discrepancies between the measured values and the reported results over the entire FS. Such errors include, but are not limited to:
 - **Nonlinearity:** The maximum deviation of the calibration points from a regression line (best fit to the data), expressed as a percentage of the rated FS output and measured on increasing load only.
 - **Repeatability:** The maximum difference between transducer output readings for repeated applied loads under identical loading and environmental conditions. It indicates the ability of an instrument to give identical results in successive readings.
 - **Hysteresis:** The maximum difference between transducer output readings for the same applied load. One reading is obtained by increasing the load from zero and the other reading is obtained by decreasing the load from the rated FS load. Measurements should be taken as rapidly as possible to minimize creep.
 - **Return to zero:** The difference in two readings: one, at no load, and the second one, after the FS load was applied and removed.

A good transducer is one with the combined (or maximum) error of less than 1% of the FS.

Analog-to-Digital Converters

In order to convey analog output (in volts) from a transducer to a computer, it has to be converted into a sequence of binary digital numbers. Modern analog-to-digital converter (ADC) boards are sophisticated high-speed electronic devices that are classified by the input resolution, as well as the range of input voltages and sampling rates.

Resolution of an ADC board is measured in bits. Bit (abbreviation for binary unit) is a unit of information equal to one binary decision (such as “yes or no,” “on or

off”). A 12-bit system provides a resolution of one part in $2^{12} = 4096$, or approximately 0.025% of FS. Likewise, 16 bits correspond to one part in $2^{16} = 65,536$, or approximately 0.0015% of FS (for tablet press applications, such resolution is usually excessive).

Thus, resolution of ADC board limits not only the dynamic range but also the overall system accuracy. Alternatively, a higher resolution may be required to retain a certain level of accuracy within a given dynamic range. For example, a 0.5% accurate transducer with 80 dB dynamic range requires at least 12-bit ADC resolution.

Amplifying a low-level signal by 10 or 100 times increases the effective resolution by more than 3 and 6 bits, respectively. On the other hand, increasing an ADC resolution cannot benefit the overall system accuracy if other components, such as amplifier or transducer, have a lower resolution.

When an input signal change is smaller than the system's minimum resolution, then that event will go undetected. For example, for an FS of 10 V (corresponding to, say, a compression transducer output of 50 kN), using a 12-bit ADC, any signal that does not exceed 2.44 mV (12.2 N) will not be seen by the system.

The ADC boards also differ by the effective sampling rate range. Sampling rate speed is measured in Hertz (times per second). The signals coming from a tablet press have a frequency of not more than 100 Hz (compression events per second). To avoid aliasing (losing resolution of the incoming signal due to slow sampling rate), the sampling rate should be at least twice the highest frequency of the signal. Most ADC boards used for data collection in tableting applications have a sampling rate of 5–20 times larger than signal frequency. That is why antialiasing filters are not required.

Computers and Data Acquisition Software

Overall accuracy of a data acquisition system is determined by the worst-case error of all its components. One should be aware of the fact that most system errors come neither from transducers (0.5%–1% accuracy) nor from A/D converters (0.025% accuracy) but from the software analyzing the data (round-off errors, improper sampling rate, or algorithms).

The speed and capacity of a data acquisition system depend on the computer's processor and hard drive specifications. The real-time data from transducers is streamlined to both the screen (for monitoring) and the disk (for replay and analysis). Generally speaking, “real-time” processing means reporting any change in the phenomena under study as it happens. Interestingly, but

a high-speed data collection from a tablet press and a bookkeeping home finance program used on a monthly basis to balance the checkbook can both be related to as “real-time” software. The difference is in the time frames. For a tablet press, we are collecting data that need to be sampled and processed in milliseconds (a typical compression event may take 25 msec), while for home bookkeeping once a month will do.

Most vendors supplying transducers, signal conditioning, and computer hardware adhere to practical standards, e.g., there are some accepted norms for strain gage factors, combined errors, sensitivity, ADC resolution, and sampling rate. The difference between vendors is apparent when we compare software because there are no universally established standards of user interface. Yet the hardware is “transparent” (i.e., invisible) to the end user—day in and day out the user is facing the screen, keyboard, and mouse. The ease of software use, bug-free analysis of signals coming from transducers, reliability of statistical computations, quality of graphs and reports, and validatability of the system—all of the above contribute to the quality of the data acquisition software.

Proper validation tests of a data acquisition system should include calculation of an overall system error when the input is known and controlled (e.g., an NIST traceable signal generator providing a sinusoidal signal with a known amplitude and frequency, to simulate compression events on a press). Comparing the output (for example, peak heights as reported by the software) to the known input, the overall system error can be reliably established.

TABLET PRESS INSTRUMENTATION FOR PRODUCT AND PROCESS DEVELOPMENT

R&D Grade Instrumentation

In a production environment, typical tablet weight control mechanism is driven by signals that are coming from a compression force transducer. Strain gages may be installed on a column connecting the upper and lower compression wheel assemblies. This transducer measures what is generally known as “main compression,” i.e., a diluted average of the forces acting on the upper and lower punches. Alternatively, a load cell may be positioned in some convenient location to register a transmitted compression force. It is measured away from the force application axis, and some force is lost in the transmission. The resulting measurement may be adequate for tablet weight control, but, even if properly calibrated, it does not represent the absolute value of the compression force.

The R&D grade instrumentation, in contrast, requires placing the strain gages as close to the punch tips as possible in a vertical alignment with the direction of force application.^[30] In practice, it means placing the gages in a compression roll pin, so that the resulting measurement would reflect the absolute force. Thus, we can differentiate between the force on the upper and lower punch, and moreover, we can compare readings of the compression force from different tablet presses.

Compression Force Measurement

On a typical R&D grade compression transducer, a compression roll pin is machined with incisions made for placing strain gages (Fig. 4). The actual form of these cavities constitutes the very art of the transducer design that is usually proprietary and is based on the know-how of instrumentation vendor.

It has to be noted that there could be an upper or lower instrumented compression roll pin.

The resulting measurement of a compression force is highly correlated with a variety of tablet properties. As compression increases, so does tablet hardness and weight (at constant thickness and true density), along with a force required to eject a tablet. Many variables affect the force of compression: press settings, press speed, punch length variation, punch wear, and damage, formulation and excipient properties.

Precompression Force Measurement

Similar to instrumented compression pin, there is a way to instrument an upper or lower instrumented precompression roll pin. Precompression, if it exists on a press, is used for de-aerating and initial tamping of the powder mass in the die and usually helps to achieve the desired hardness without capping or lamination.^[30,31] The force

Fig. 4 Compression force transducer.

Tablet Press Instrumentation

of precompression is normally a fraction of the compression force.

Ejection Force Measurement

There are many ways to instrument an ejection cam. A preferred arrangement of strain gages (the so-called “shear force” design) does not require any discontinuities in the cam surface, and, most importantly, it provides for a very good linearity of the resulting signal (Fig. 5).

Larger ejection forces may lead to an increased wear on tooling and eject cam surface. Ejection force may also be used to evaluate the effectiveness of lubrication (of both the press and the product) and punch sticking. Sensitivity and linearity of an ejection transducer are design dependent: shear force designs are always preferable over split cam or cantilevered beam designs.

Take-Off Force Measurement

Take-off force is monitored by mounting a strain gage to a cantilever beam on a press feed frame (in front of the take-off blade, Fig. 6). It is done to measure adhesion of tablets to lower punch face. Such adhesion is indicative of underlubricated granulation, poor tooling face design, die-wall binding, and tablet capping.^[32,33]

Speed Measurement and Station ID Determination

Station identification and press speed are usually obtained by means of a revolution counter (proximity switch). It is installed on the press in order to mark the beginning of a turret revolution and thus enable station identification and speed calculations by system software.

In addition, a linear arrangement of proximity switches can mark the beginning and end of a compression event

Fig. 5 Instrumented ejection cam.

Fig. 6 Instrumented take-off bar.

(information that is vital for tablet weight controllers) and also indicate missing punches.

Other points of instrumentation on a tablet press are as follows:

- A rotary press pull-up cam can be instrumented to measure the upper punch pull-up force (the force required to pull up the upper punch from the die). Likewise, the lower punch pull-down force is measured on a bolt holding the pull-down cam.^[34] It is useful in determining the smoothness of press operation (extent of lubrication, cleanliness of the machine, and long batch fatigue buildup).
- Punch displacement measurements are easily done on a single station press by attaching LVDT to the punch. On a rotary press, such measurements can be done by means of slip ring, telemetry, or instrumented punch. Punch displacement profiles may be used in conjunction with compression force to estimate work of compression and work of expansion (measure of elasticity). Because capping tendency increases with the punch penetration depth, it may be desirable to monitor actual punch movement into the die. The shape of a force–displacement curve is an indication of the relative elasticity or plasticity of the material; whereas plastic deformation is desirable for stronger tablets, excess plasticity usually results in tablets that tend to cap and laminate.^[35–37]
- Radial and axial die-wall force measurements also provide an insight into the compaction mechanism of the material and may indicate a die-wall binding (sticking) that is, in effect, a negative pull on lower punch. The radial die-wall pressure due to friction is material-specific and is more evenly distributed inside the die with an addition of a lubricant.^[38–44] Instrumentation of the die presents a technological challenge because pressure is distributed nonlinearly

with respect to tablet position inside the die and depends on tablet thickness.^[45,46]

- In-die temperature can be monitored for heat-sensitive formulation, such as ibuprofen.^[47,48]

Instrumented Punch

Several vendors offer instrumented punch, i.e., a punch that has strain gages and other instrumentation built-in. The data are then accumulated or transmitted via telemetry to a stationary computer. Such devices are versatile enough to report compression forces and either punch displacement or acceleration, and, at least in theory, they can be easily moved from press to press.^[49,50] However, one should keep in mind that each instrumented punch is limited to one size and shape of the tooling, and is limited to one station, compared to roll pin instrumentation that reports data for all stations and any tooling. In addition, instrumented punches are either rather cumbersome to install, or else they report a useless measurement of punch acceleration instead of punch displacement. Attempts to calculate displacement from acceleration so far could not be validated.

Single Punch Press for R&D

Single punch eccentric presses are often used in early stages of formulation development because they do not require a large amount of powder. Another benefit is that they allow relatively inexpensive measurements of die forces and punch displacement (there is no rotation of die table and therefore no need to use expensive telemetry methods). This is the primary reason why so much basic research and product development were done on eccentric machines.^[51] Negative considerations are that a special tooling is required (usually, F tooling), and also that speed of compaction is too slow compared to rotary presses. As it will be seen later, the speed is a crucial factor in tableting process and therefore the results obtained on single punch presses do not directly correlate with tablets made on rotary machines.

Benefits of Press Instrumentation

Among many benefits of press instrumentation, formulation fingerprinting is perhaps the most obvious. Compressibility and ejection profiles, as well as dissolution and disintegration curves related to compression force, are unique for each formulation and can be used as a batch record. For process optimization, one can include compression or precompression force and speed factors in

experimental design. Compactibility and ejection profiles can be used for excipient and lubricant evaluation. Other useful product development and optimization tools include response surface, Heckel, and force–thickness plots.

Scientifically reliable process scale-up cannot be achieved without instrumentation data providing scale-up parameters such as dwell time, density, and energy of a tablet.

In a pilot plant and on the production floor, proper instrumentation can be used for press troubleshooting, to warn about tooling irregularities, worn-out cams, sticking punches, underlubricated dies, and so on. Finally, instrumentation is widely used for tablet weight control.

Instrumentation for Formulation Development

Much of the current body of knowledge about compaction properties of pharmaceutical materials came from instrumented tablet presses.^[52–56] Many tablet properties, such as tensile strength (hardness) and porosity can be predicted from force profiles.^[57–59]

Work of compaction (a scale-up parameter) can be obtained with proper instrumentation.^[60,61] Information about the plasticity of materials can be derived from force–time curves.^[62–64]

The phenomenon studied with the help of instrumentation is the so-called “lag time” (the time difference between peak of compression and maximum punch penetration). The extent of this lag is indicative of compaction mechanisms of the powder being compressed.^[65,66]

Typical waveform

Let us have a look at the actual waveforms that one may obtain from an instrumented tablet press (Fig. 7). The black proximity switch trace that marks the beginning of a revolution should be noticed. On this press, precompression and compression events coincide in time (they relate to different punches, of course). They are followed by the ejection and take-off.

Compactibility profile

When the average tablet hardness is plotted against the average compression peak force, we get the so-called compactibility profile that allows us to compare different formulations or different processing speeds. Referring to Fig. 8, which formulation is better? Well, formulation No. 2 makes harder tablets for the same compression force, and this would mean less wear and tear on the production press is required to achieve desired hardness. On the other

Fig. 7 Typical compression, precompression, and ejection waveforms.

hand, if the hardness tolerance limits are exceptionally narrow, the steeper slope of formulation No. 2 may be a detriment.

Lubricant profile

A certain quantity of lubricant must be present in the granulation to reduce the friction that occurs at the die wall as the tablet is being ejected, as well as to prevent sticking of the tablet to the face of the punches. Without instrumented ejection cam and take-off bar, no objective estimate of an optimal lubricant level is possible, and the “best” formulation is usually the last one prepared.

The plot shown in Fig. 9 will help a formulator to determine the optimal amount of lubricant. Obviously, one would try to minimize the ejection force (again, to reduce wear and tear on the ejection cam of the production press), and yet to avoid the pitfalls of having too much lubricant in the formulation.

Because of the natural association of lubricant properties with lipophilic materials, formulations containing high levels of lubricant can show retarded dissolution of the

active ingredient and the slow dissolution rate could adversely affect the in vivo bioavailability of the drug.

Lubricant study

Another important use of ejection force transducer is the evaluation of lubricants (either different chemically, or similar lubricants coming from different vendors).

As shown in Fig. 10, the preferred lubricant is No. 1 as it results in a smaller ejection force. Early lubricant studies are a must. When lubricant problems occur later on in the scale-up process, corrective measures not only require additional materials and development time, but may also require a supplement of an approved new drug application (NDA).

Response surface plot

Formulation and process optimization can be done statistically with the use of experimental design for estimates of the best processing parameters and excipient

Fig. 8 Compactibility profile.

and lubricant levels. Controllable variables in tableting are mainly the precompression and compression forces and tablet press speed, as well as the formulation component levels. Response variables include the ejection force, tablet hardness and friability, dissolution rate, and drug stability. The purpose of an experimental design is to perform a series of experiments in order to determine some levels of factors that will allow us to achieve an optimal

level of dependent variables. The experiments should be designed so as to minimize effort and maximize statistical reliability of the results. Published work in this area deals mostly with response surface designs that produce a predictor polynomial equation for each response variable under consideration. A multidimensional surface is then searched for the best ranges of factor variables that, when plugged in the equations, result in the optimal value of the

Fig. 9 Lubricant profile.

Fig. 10 Lubricant study.

responses. In this plot (Fig. 11), the optimal (highest) hardness is obtained when the compression force is in the range 3000–4000 lb with as much MCC in the formulation as possible.^[67]

Compactibility study—elastic recovery

Many powders, especially with viscoelastic compaction mechanism, such as starch or avicel, exhibit large degree of stress relaxation (with time-dependent deformation).

If you monitor punch displacement and compression force, you can make pretty accurate assessment of the compactibility of your material. If LVDTs are attached to both upper and lower punches, it is possible to actually measure in-die thickness of the tablet at various compression levels. In Fig. 12, one can see how the tablet thickness rapidly decreases in the compression stage and then gains some thickness during the decompression stage of the tableting cycle. The degree of this increase in

Fig. 11 Response surface plot.

Fig. 12 Compactibility study—elastic recovery.

thickness is indicative of the elastic recovery as the pressure is removed from the tablet.

Elastic recovery and work of compaction were studied extensively using instrumented tablet presses.^[68]

Compactibility study—Heckel plot

In 1961 Heckel^[69,70] postulated a linear relationship between the relative porosity (inverse density) of a powder and the applied pressure. The slope of the linear regression is the Heckel constant, a material-dependent parameter inversely proportional to the mean yield pressure (the minimum pressure required to cause deformation of the material undergoing compression). Large values of the Heckel constant indicate susceptibility to plastic deformation at low pressures, when the tablet strength depends on the particle size of the original powder. The intercept of the line indicates the degree of densification by particle rearrangement (Fig. 13).

Fig. 13 Heckel plot.

TABLET PRESS INSTRUMENTATION FOR PROCESS TROUBLESHOOTING

Typical problems in tableting include weight variation, capping, lamination, tooling irregularities, die binding, picking, and sticking. Most of such problems can be detected and/or resolved using proper instrumentation.

Upper and Lower Compression

Fig. 14 shows a typical set of upper and lower compression profiles. One can see that the lower trace is smaller than the upper. On a single station press, only the upper punch is usually moving, and the difference is caused, mainly, by the friction of the compressed powder inside the die.

On a rotary press, both punches are moving and therefore the friction of the punches inside the turret and the die causes the difference. The lower punch fits the turret with a larger standard clearance compared to the upper punch. In addition, the lower punch is never leaving the die, while the upper punch leaves and enters the die with each stroke. This results in a comparatively better alignment and lower friction. The close fit of the upper punch does not allow it to penetrate the die smoothly and this can cause the increase in friction. Thus, an excessive difference between the two peaks may indicate an underlubricated die or some punch misalignment problem.

Histogram of Punch Performance

Similar irregularities in punch tolerances become even more visible on a bar histogram where each bar corresponds to peak force produced by each punch (Fig. 15). As the new revolution arrives, the bar lengths

Fig. 14 Upper and lower compression force vs. time.

Fig. 15 Histogram of compression force per punch.

are adjusted. If a particular bar persists in being taller or smaller than the rest, it means the presence of a long or short punch.

Press Monitor—Real-Time Screen

On this real-time screen (Fig. 16), one can clearly see that there is an abnormal ejection event in the first station after the proximity switch. This is a clear indication of a sticking punch or a similar problem. In addition, the first compression peak is somewhat taller than others. This may be caused by a long punch.

TABLET PRESS INSTRUMENTATION FOR PROCESS SCALE-UP

Scale-Up Factors

One of the main practical questions facing formulators during development and scale-up is: Will a particular formulation sustain the required high rate of compression force application in a production press without lamination or capping? Usually, such questions are never answered with sufficient credibility, especially when only a small amount of material is available and any trial and error approach may result in costly mistakes along the scale-up path.^[71]

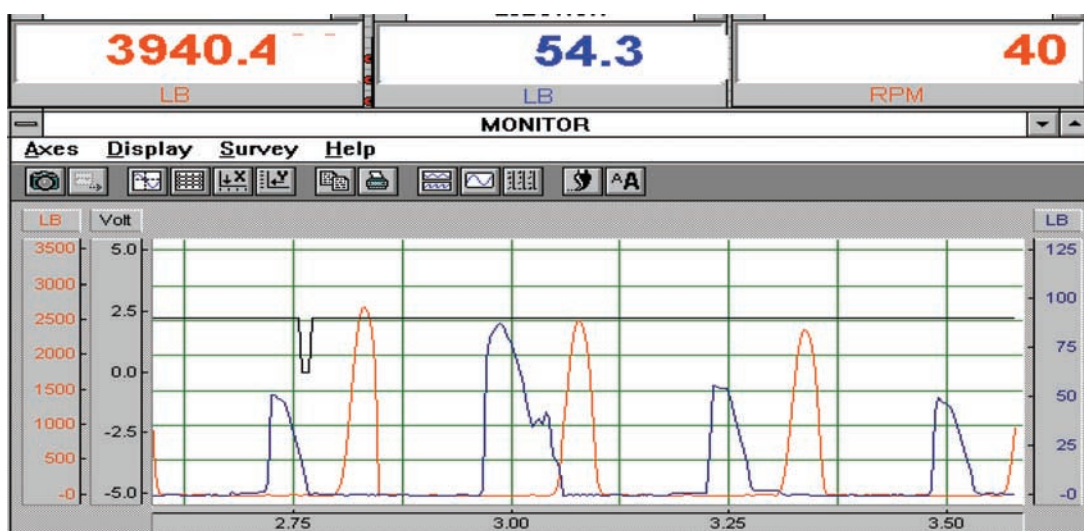

Fig. 16 Real-time screen.

As formulations are moved from small-scale research presses to high-speed machines, potential scale-up problems can be eliminated by simulation of production conditions in the formulation development lab. One way to eliminate potential scale-up problems is to develop formulations that are very robust with respect to processing conditions. A comprehensive database of excipients detailing their material properties may be indispensable for this purpose. However, in practical terms, this cannot be achieved without some means of testing in production environment and, because the initial drug substance is usually available in small quantities, some form of simulation is required on a small scale. Studies of tableting process on a class of equipment, generally known as compaction simulators, are designed to facilitate the development of robust formulations. However, simulators are rarely used to simulate tablet presses for reasons that will be explained later.

In any process transfer from one tablet press to another, one may aim to preserve mechanical properties of a tablet (density, and, by extension, energy used to obtain it) as well as its bioavailability (e.g., dissolution that may be affected by porosity). However, a formulation that was successfully developed on a single station or small rotary press may not stand up to the challenges of scale-up because tablets that were meeting all specifications in the lab or clinical studies may exhibit capping or lamination at higher speeds.^[72,73]

Compression force magnitude and the rate of force application are the most important variables in tableting scale-up.

Force factor

The compression force is the dominant factor of the tableting process. It is directly related to tablet hardness and friability, and is correlated with the phenomena of lamination and capping.

It was also shown to have effect on disintegration times and dissolution profile.

Speed factor

As the punch speed increases, so does the porosity of tablets and their propensity to capping and lamination. The tensile strength of compacts tends to decrease with faster speeds, especially for plastic and viscoelastic materials, such as starch, lactose, avicel, ibuprofen, or paracetamol. Such materials have the tendency to cap or laminate at higher speeds.^[74–88]

The notions of dwell time and contact time, to be discussed in detail later, are the common indicators of press speed and the rate of force application.

Force profile factor

In addition to the level of force and the rate of force application, the shape of the compression force vs. time curve is of a paramount importance because it directly affects tablet properties such as hardness and friability. It is a known fact that the compression part of the compression cycle (during the “rise time” of the force–time profile) is 6–15 times more important than the decompression part as a factor contributing to capping and lamination. On the other hand, reducing the decompression part of the cycle results in the increase of tablet hardness by reducing the extent of elastic recovery.^[89] Alternatively, reducing the compression part of the cycle results in no change of tablet strength for viscoelastic materials and increased hardness for brittle materials.

Other Considerations

Numerous other factors may affect the scale-up process. The quality of the measurements, variation in tooling, powder properties, and tablet weight are some of those factors.

- Instrumentation grade.
- Measurement of speed.
- Measurements of mechanical strength.
- Tooling variation.
- Powder flow variation.
- Excipient/raw material variation.
- Tablet weight variation.

Dwell Time and Contact Time

Matching tablet press speed (rpm) of the research and production presses has, of course, no meaning, because of different number of stations and pitch circle diameter. It is vital, therefore, to translate the rpm into dwell time or contact time.

Many investigators have reported the effect of dwell times and strain rate sensitivity on the compaction of various excipients, especially viscoelastic materials.^[90–94] There are at least two definitions of dwell time in practice today.

Functional definitions

Functionally, the effective dwell time (EDT) at 90% level can be defined as the time it taken by the force–time curve

to traverse the 90% of the peak height. Likewise, the effective contact time (ECT) is the time between points at 10% of the peak height. The shape of the force curve depends, as we know, on the deformation mechanisms of the powder and therefore, all other variables being equal, EDT and ECT will be different for brittle and plastic materials. Although somewhat useful for material characterization, such variables should not be confused with the universally accepted definitions of contact time (time of contact) and dwell time (time of immobility).

Mechanical definitions

Mechanical Definitions of dwell and contact times disregard material properties and concentrate on press and punch geometry (Fig. 17). Contact time can be defined as the time the punch is in contact with the compression wheel. Dwell time is defined as the time the flat portion of punch head is in contact with the compression wheel (time at maximum punch displacement, or time when the punch does not move in vertical direction). In dwell time calculations, the length of the punch head flat and horizontal component of punch speed (as determined by RPM and pitch circle diameter) are used. In case of a round head tooling, the dwell time, as defined here, is zero. But it should be kept in mind that mechanical definition is given here as a convention, a yardstick, or a common measure, to compare press speeds for different presses, and its absolute value is meaningless. A proposed convention to quantify linear speed of a press is to use an Industrial Pharmaceutical Technology (IPT) Type B tooling with a known punch head flat as a standard for press speed comparisons.

In what follows, we will use the mechanical, rather than functional, definitions because they serve as an objective material-independent measure of compaction speed.

Dwell time comparison for different presses

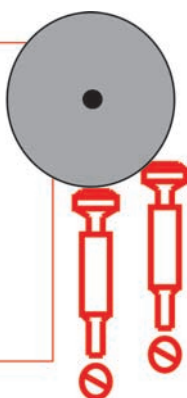

Comparing the dwell time ranges for a number of presses can be a gratifying experience. Here one can see that even for the same brand name, there is a wide distribution of ranges. It has to be noted that proper scale-up will be possible only when the ranges overlap. Dwell time range may also be used to classify or identify tableting equipment. The dwell time ranges vary considerably in various tablet presses. As shown in Fig. 18, Manesty Betapress is positioned well within the range of production speeds of the high-speed presses. That is, probably, why this press is often used for R&D work. On the other hand, small presses such as Korsch PH106 or Piccola do not even come close to benchmark production speeds of 6 msec–15 msec in terms of dwell time. The MCC Presster™ can reach the production dwell times while making one tablet at a time.

Dwell time vs. production rate

For a benchmark production speed of 100,000 tablets per hour (Fig. 19), dwell time distribution follows an inverse power relationship, which is expected because dwell time is a reciprocal function of the press speed. In general, all production presses should be qualified with respect to dwell and contact times per benchmark output. Ideally, product development must be done on a laboratory press that can match (in terms of the dwell time) the target production output.

Dimensional Analysis of Tableting Process

Dimensional analysis is a method for producing dimensionless numbers that completely characterize the process. It is widely used in many areas, including chemical engineering and pharmaceutical industry.^[71] Because all

$$DT \text{ (msec)} = \frac{L \cdot NS \cdot 3,600,000}{\pi \cdot PCD \cdot TPH}$$

L = Length of a flat portion of the punch head (mm)
 NS = Number of Stations
 π = 3.14159265
 PCD = Pitch Circle Diameter of the turret (mm)
 TPH = press speed in terms of Tablets Per Hour

Fig. 17 Dwell time and contact time—mechanical definitions.

Fig. 18 Dwell time comparison for different presses.

the dimensionless numbers necessary to describe the process in similar systems must have the same numerical value,^[95] matching such values on different scales is a sure way to success in any scale-up operation. This dimensionless space in which the measurements are presented or measured will make the process scale invariant.

In tableting applications, the process scale-up involves different speeds of production in what is essentially the same unit volume (die cavity in which the compaction takes place). Thus, one of the conditions of the theory of models (similar geometric space) is met. However, there are still kinematic and dynamic parameters that need to be investigated and matched for any process transfer.

Scientifically sound approach would be to use the results of the dimensional analysis to model a particular production environment to facilitate the scale-up of tableting process, by matching several major factors, such as compression force and rate of its application (punch velocity and displacement) in their dimensionless equivalent form.^[96]

TABLET PRESS AND COMPACTION SIMULATORS

It can be seen that, as a rule, tablets are formulated at speeds that are very slow compared to production. If

Fig. 19 Dwell time vs. production rate.

simulation of a production press is required to minimize the scale-up effort, some way of speeding up the tableting process in development is required. Once the linear speed of the punch is attained, the rate of force application (i.e., the instantaneous change in compression) should also be matched. This is, of course, an infinitely more difficult task.

Hydraulic Compaction Simulator

A small number of devices known as compaction simulators exist in the world. Invented more than 20 years ago, they become popular in basic compaction research. A wealth of studies have been generated in the last 20 years.^[97–117]

Compaction simulators (Fig. 20) were designed to mimic the compression cycle of any prescribed shape by using hydraulic control mechanisms that are driving a set of two punches (upper and lower) in and out of the die. All hydraulic compaction simulators are similar in design and construction. A compaction simulator consists of several main units: the load frame (column supports and crossheads with punches), the hydraulic unit (pumps and actuators that move the crossheads), and the control unit (electronic console and computer). Usually, a simulator

Fig. 20 Schematic depiction of a compaction simulator.

accepts F tooling only, but can be retrofitted to use standard IPT B tooling. Under computer control, the hydraulic actuators maintain load, position, and strain associated with each punch.

The simulation can be achieved by one of the two procedures: matching either the force (load control) or the movement of punches (position control) at any given moment of time. Thus, when running a simulator, one has a choice: to mimic the force/time path (compression profile) or the motion of the punches (punch displacement curves). It is impossible to mimic both at the same time on any hydraulic compaction simulator.

Load control profile

Matching the force–time profile of a production tablet press is the primary goal of any tablet press simulation. However, the rate of force application and the shape of the resulting signal are not usually known in advance. The compression profile (force vs. time) is impossible to calculate theoretically because it has a different shape for different materials and tooling.

Using an instrumented punch to collect force data is cumbersome because it is limited to a particular punch size and shape. Recalculation to pressure values is not always adequate. One can, however, monitor and record force waveform from a properly calibrated R&D grade compression transducer. Once the production press brand, model, speed, and tooling are specified, a waveform can be recorded and then fed into hydraulic simulator.

This approach is impractical for formulation development work because one would need to record force waveform on a rotary press using formulation similar to the one being developed. Usually, there is no such powder available and the actual formulation being developed is available in limited quantities.

Position control profile

Because load control profiles are not practical, users of hydraulic compaction simulators overwhelmingly prefer to utilize punch displacement profiles in hope that, once the punches are forced to move in the same pattern as in the production press, the force–time curve will follow. For example, a recently built laboratory compaction simulator does not have a force control functionality at all.^[118]

There are three possible sources of the punch position trace:

- Prerecorded data.
- Artificial profiles.
- Theoretical profiles.

To obtain a position control profile from any tablet press, one has to record the movement of the punches using LVDT. Besides the technological challenge that this objective may present, the punch movements on a press depend on many factors, including brand name and model of the press, speed of the turret, shape of punches and die, size and shape of the tablet, and most importantly, compaction properties of the powder. The problem with this is that data from production presses are inevitably obtained using material other than the one being developed. It is a vicious circle: the profiles before developing a formulation and the formulation before obtaining punch displacement profiles are needed.

Many compaction studies were done on compaction simulators using artificial punch displacement profiles, for example, the so-called “single-ended” profile, i.e. when the lower punch is stationary (like in a single station press). Other studies were using a “saw tooth” profile, i.e., a constant speed profile where punch displacement speed is constant at any given time interval under load. It is obvious that such profiles have nothing to do with simulation, although they provide a degree of uniformity for basic compaction studies. The very name “compaction simulator” is a misnomer as is acknowledged by a number of researchers in the field. The machine is best described as a compaction research system because it is well suited for the basic compaction studies (densification and bonding properties of materials).

To simulate tablet presses, compaction simulator users most frequently employ the theoretical position control profiles. Theoretical path is calculated from the geometry of the press and punches, using the radius of the compression roll, the radius of the curvature of the punch head rim, the radius of the “pitch circle” (distance between turret and punch axes), and the turret angular velocity.^[119]

The resulting sinusoidal equation is used in order to “simulate” punch movement in a tablet press.

In practice, theoretical and actual punch displacement profiles on a rotary press have very little in common because the theoretical profile does not account for several mechanical factors, such as punch head flat. Moreover, the punch movement equation was derived for a punch moving in and out of an empty die. The effect of material resistance to pressure and elastic recovery is not accounted for in the equation. The discrepancies between the calculated and real punch movements are rather striking.^[120–122]

In addition, it was shown that the lower and upper punches may not move synchronously. Moreover, maximum force does not coincide in time with the minimum punch gap.^[123] These and other considerations (press deformation, contact time, etc.) make the effort of simulating a production press on a hydraulic compaction

simulator rather impractical. That is why, to quote from a paper by Muller and Augsburger,^[124] “Although compaction simulator have been designed to mimic the displacement time behavior of any tablet press, they rarely have been used in that fashion.”

Literature sources reporting the use of compaction simulators in simulating actual tablet presses are rather scarce. Some studies suggest that, for whatever reason, tablets made on a Manesty Betapress were significantly softer than those made on a compaction simulator using the theoretical Betapress punch displacement profiles.^[120,125]

To summarize, one can say that hydraulic compaction simulators are ideally suited for basic compaction research but are not very practical for simulation of production presses.

Tablet Press Replicator: The Presster™

Recently, a new type of machine was introduced to mimic production presses on a small scale. Known under a brand name of “Presster”—kind of an agglomeration of the words “press,” “presto,” and “tester”—this machine can be classified as a mechanical compaction simulator.

The Presster™ is a high-speed single station press that is also a tablet press simulator (Fig. 21). It was designed to simulate production presses without any use of hydraulic controls, and, consequently, there is no need to feed in any artificial, theoretical, or prerecorded punch displacement profiles. Built around a linear carriage that moves a set of punches and a die between two compression rolls, it can mimic press geometry by matching the compression wheels match press speed using a variable speed motor drive match tablet weight and thickness by adjusting depth of fill and the distance between the rolls match tooling by installing standard IPT or any special tooling.

Thus, using mechanical similarity, all of the scale-up fact are matched, namely, the compression force, the speed, and the shape of the force profile. To use Presster, first a production press to be simulate should be selected, and the compression wheels with a matching diameter should be installed. Then, production speed should be selected in terms of tablets per hour, RPM, or dwell time. The Presster™ will mimic the selected production press speed and compression force profile and will allow us to make one tablet at a time.

As a high-speed single station press, mechanical compaction simulator will be able to plot compressibility profiles, Heckel graphs, calculate work of compaction, and virtually any other imaginable variable that is of interest to formulators. Tensile strength of tablets made on a Betapress and The Presster™ was similar.^[126]

Fig. 21 Tablet press replicator: The Presster™.

Precompression and ejection steps of the tableting cycle can be included in simulation. Some current limitations of Presster should be pointed out: It will neither follow any artificial punch movement profile, nor will it address, at least in its present implementation, the issues of feeding and die fill at high speeds, or speed-related temperature fluctuations.

PRESS INSTRUMENTATION AND CONTROL ON THE PRODUCTION FLOOR

Tablet Weight Control and Tablet Force Control

To keep tablet weight within the prescribed tolerance limits, the required instrumentation includes compression transducer and several proximity switches for station identification and pinpointing the compression event. Tablet weight controller can be just one, albeit a major, unit of a larger press automation system. Press automation system may include:

- Tablet weight control.
- Material handling interface.
- Feeding system.

- Collection system.
- Packaging system.
- Supervisory control (SCADA) station.

The latter can be a computer positioned on the supervisor's desk that monitors the performance of each press on the production floor, with timely status report for each batch.

There are many reasons why it is imperative to control tablet weight variation:

- Production costs are lowered because there is less waste.
- Productivity is increased because there is a better equipment utilization.
- Batch-to-batch variability is minimized for obvious reasons.

When the cost of each out-of-spec wasted tablet is significant, the savings produced by weight control quickly add up. Product quality is improved when there is less of a chance to get an out-of-spec tablet into the acceptable batch. Last, but not least, is the improved safety because the automated process requires less human intervention.

Control mechanisms

For constant tablet thickness, in a small target area of tablet weight, compression force is directly proportional to tablet weight. Force control systems maintain compression force within prescribed limits by adjusting the depth of fill cam. The limits are established empirically for each formulation recipe.

Alternatively, a weight control system would require an expressed correlation between force and tablet weight. A few tablets at different force levels can be made to correlate the resulting tablet weights with the force values. Next, one can express tablet weight tolerance limits in terms of the compression force. The weight control system can adjust the dosing to keep the tablet weight within the desired limits. For this control theory to work consistently, one needs to recalibrate force–weight relationship periodically, as the powder properties and tablet mechanical condition can vary in time.

Control functions include alarm and shutdown (when any individual force peak or revolution average exceeds preset limits), force or weight control (usually done on revolution average only), and rejection of out-of-spec tablets. With a mechanical gate, usually several tablets are rejected at a time, with the bad tablet being rejected along with the adjacent good tablets. With a fast pneumatic–air stream rejection mechanism, the control system can pinpoint and reject one bad tablet only.

Control criteria

Control decisions are usually done as follows:

1. Adjust depth of fill cam if revolution average is outside some redefined acceptable limits.
2. Reject each tablet that exceeds individual limits or if the press speed slows down beyond some level.
3. Sound an alarm if the same station repeatedly produces bad tablets or if revolution average exceeds alarm limits.
4. Shut down the press if any tablet is made with a force exceeding the shutdown limits, or if revolution average is outside the shutdown limits.

Control algorithms

One-point control is a description of a control when any deviation of the compression force from a preset target level results in a corrective action of the dosing cam. This action can be proportional (P) to the deviation from the target, or it could be correlated with the integral (I) of

the deviation over some time, or it could be tied in with the rate of change (D, for derivative) of the compression force. This would correspond to proportional, integral, or derivative control types, respectively. There also can be a combination of the control types. Thus, one can have P, I, P + I, P + D, and P + I + D control algorithms.

Alternatively, a two-point control is enacted when the compression force is outside an acceptable band outlined by the upper and lower tolerance limits. Thus, there are separate control limits, rejection limits, alarm limits, and shutdown limits, and no respective action is taken when the signal is inside these limits.

Strictly speaking, one-point control can be viewed as a special case of the two-point control when the bandwidth of the control limits is tightened to approach zero.

Control Systems

Original equipment manufacturer (OEM) control systems

Almost each tablet press manufacturer offers a system that is designed to control the press. Some of these systems are very sophisticated devices that monitor and control a vast array of tableting functions. If, however, there are several brand names on the production floor, any standards in the control system implementation for different manufacturers should not be expected. Likewise, software interfaces exhibit quite a range of user-friendliness.

In one brand name press, tablet weight control is achieved by regulating the dosing cam based on powder bed thickness in the precompression cycle. This clever approach is possible because precompression force is kept relatively constant by means of pneumatic compensating mechanism. Under these conditions, tablet weight is directly proportional to thickness. The subsequent compression cycle can be done to constant thickness, like on any other press.

Generic control systems

An alternative to OEM control systems is generic controllers that may offer plug-in compatibility with the brand name controllers and may provide a degree of standardization.

However, such generic controllers may lack the degree of sophistication and versatility of the controllers that are made by the press manufacturers. One thing to keep in mind is that not all control systems are created equal, but all control systems use the same principles.

A decent tablet weight control system should be based on product recipes, provide instant display of compression force distribution, control charts and batch reports on

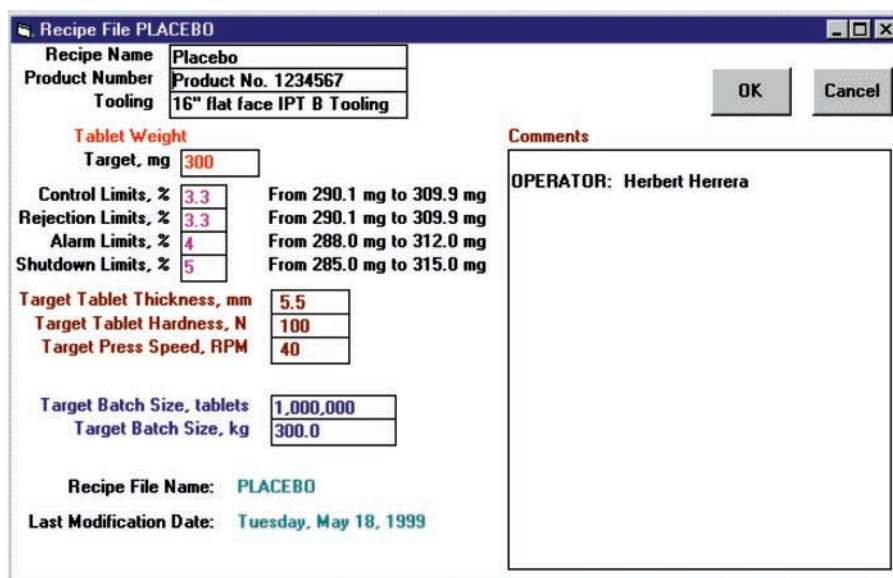

Fig. 22 Recipe example.

demand, archiving data for subsequent analysis or documentation, give some measure of standardization, be fully compliant with current validation requirements, and provide a multilevel security, e.g., password protection for operator and supervisor when they need to change recipes, etc. Some examples of displays, available to operators of instrumented production presses equipped with controllers, follow.

Recipe example

In Fig. 22, an example of a typical control recipe with dosing cam adjustment, rejection, alarm, and shutdown limits expressed as a percent deviation from the target

tablet weight is shown. The software then converts all values into the corresponding compression force levels for control purposes.

Bar histogram

This chart is similar to one used in tablet press monitoring for press troubleshooting (Fig. 15). It is vital for any production press operator.

Control chart

Control chart is a simple graph of peak compression force vs. time. Each point on the chart corresponds to the

Fig. 23 Statistical process control X-bar chart.

average of N tablets made, with N ranging from 1 to several revolutions. The horizontal lines would indicate the control limits.

Statistical process control chart

Statistical process control (SPC) chart (Fig. 23) of the averages is another “must have” real-time display. Each point on the chart represents a revolution average of the compression forces or corresponding tablet weights. The limit lines are calculated at one standard deviation of the mean, and there are certain rules that are used to determine when and if the process gets out of control. These rules are available in any textbook on the SPC.

Tablet Testing

Saeed A. Qureshi

*Therapeutic Products Directorate, Health Canada, Tunney's Pasture,
Ottawa, Canada*

INTRODUCTION

A tablet is perhaps the oldest and most common pharmaceutical dosage form. Its popularity is due to its convenience in the administration of a drug without the help or supervision of a health care practitioner, thus providing patients' freedom and a very cost-effective means of providing a reproducible medication. A tablet seldom consists of only the active ingredient. In fact, a tablet represents a mixture of one or more active ingredient(s) with a number of "inactive" ingredients or excipients. There are many reasons for formulating a tablet product with excipients, ranging from management of small dosage amounts of active ingredient to esthetic reasons of color and shape of a product. However, the most fundamental and critical objective of a tablet product is to provide/deliver the active ingredient accurately and reproducibly. Therefore, from this perspective, a tablet is now commonly considered as a drug delivery device. There has also been an increased emphasis in developing tablets that provide, unlike the conventional-release tablets that are of fast disintegrating/release characteristics, controlled disintegration/release process of the active ingredient. These tablet products are therefore known by different names, such as slow-, extended-, controlled-, sustained-, or delayed-release tablets to reflect their drug release characteristics. These modified drug release products provide further convenience to patients by reduced frequency of drug administration, e.g., once a day instead of three doses per day, thus increasing chance of compliance as well. However, for establishing the quality of a tablet product, the fundamentals remain the same, i.e., to ascertain that the product delivers the intended active ingredient in an accurate and reproducible manner. Therefore, tablet testing can be broadly divided into three aspects or categories:

1. Confirmation of the nature of the active ingredient and the product (identity, quantity, impurities, integrity, etc.).

2. Establishing pharmaceutical availability of the active moiety both in vitro and in vivo in humans and, if required, also in animals.
3. Establishing stability profiles to achieve shelf life.

This article provides an overview of the current techniques used for this purpose and discussion of the generally accepted standards. Using conventional-release products as a model product and North American standards/specifications, logistics of conducting testing and the general practices and instrumentation used are described. Relevant references are also provided^[1-4] for further and specific details of testing products and possible differences in national and regional guidelines.

TESTING OF NATURE OF THE TABLET PRODUCTS

In this category, one seeks to establish whether the tablets are within specifications, for example, the nature of the active ingredient (identification), expected amount (assay), purity (related compounds), and uniformity of the amount of drug from tablet to tablet (uniformity of dosage units). Commonly these testing procedures are described in pharmacopeias under a specific name, for example, the names given in parentheses are referred to as the USP (U.S. Pharmacopeia) terminology. In addition to these tests, some other tests such as friability, hardness, disintegration, etc. are also conducted and are described below. Although a number of procedures could be described for individual tests, most emphasis will be given to procedures described in the pharmacopeias because these are usually relatively simpler to conduct and are generally recognized around the world.

Identification

The first and foremost important test in tablet testing is to establish that the tablets contain the labeled active ingredient. For this purpose, usually a fixed number of tablets, e.g., 10–20, are ground and extracted with appropriate solvent extraction. The extract, with or

without a concentration step, is usually chromatographed along with an authentic standard solution. The identity of drug is confirmed based on similarity of ultraviolet (UV) spectrum and/or retention times using chromatographic analysis. This test is generally qualitative in nature. More sophisticated techniques such as chromatographic techniques with or without coupling with mass-spectrometry may be used. However, for routine quality control purposes, the simpler techniques such as thin layer chromatography (TLC) or high-performance liquid chromatography (HPLC) with UV detection are mostly employed.

Assay

One may assume that this test as a quantitative version of the identification test. Again, 10–20 tablets are ground and the active ingredient is dissolved or extracted in a suitable solvent using the described procedure. The concentration of the extracted solution is determined using a specific and validated spectroscopic or chromatographic method against a solution of reference standard. These results are reported as percent of expected/labeled value. Although the specifications for assay results differ from product to product, generally the expected range for individual active ingredient is to be within 90%–110% of the labeled amount.

Uniformity of Dosage Units

This test is conducted to establish consistency in the content of active ingredient from tablet to tablet. There are generally two approaches taken in establishing this: weight variation or content uniformity.

If the active ingredient represents not less than 50% weight of the tablet and greater than 50 mg, then one may establish uniformity of dosage units using the weight variation method. A sample of 10 tablets are weighed individually and results of these weighing are recorded.

In the case of the content uniformity approach, a sample of 10 tablets are individually analyzed using the analytical method described under the assay procedure. It is mandatory to use content uniformity for tablets with less than 50 mg of active ingredient and/or representing less than 50% total mass of the tablets. The content uniformity approach is preferred over the weight variation approach as it more precisely reflects the variation of the active ingredient from tablet to tablet.

The required specification for this test is that uniformity of dosage unit should be within a range of 85%–115% with a relative standard deviation of less than or equal to 6%.

Impurities

The impurities present in a tablet product may fall under different categories, such as: foreign substances that are introduced by contamination or adulteration; toxic impurities that have significant undesirable biological activity, even as a minor component, and require individual identification and quantitation by specific tests; concomitant components that are characteristic of many bulk pharmaceutical preparations, but are not considered as impurities, for example, optical and geometrical isomers; ordinary impurities are those that are innocuous by virtue of having no significant biological activity in the amount present. These impurities may arise out of the synthesis, preparation, and/or degradation of the product.

Generally, most of the impurity profile is established from bulk pharmaceutical material (the raw material). However, from the finished product perspective, products are only analyzed to the extent of toxic impurities. In this case, usually it must be established that product is either free from the specific impurities or the impurities are within acceptable specifications.

Friability

This test is intended to determine, under defined conditions, the friability of uncoated tablets, the phenomenon whereby tablet surfaces are damaged and/or show evidence of lamination or breakage when subjected to mechanical shock or attrition. Commercially available apparatuses known as friabilators are used for the test. Basically, it consists of a drum with diameter between 283 mm and 291 mm and having width of 36 mm–40 mm, made of transparent plastic material (Fig. 1). The drum is attached to the horizontal axis of a device that rotates at 25 ± 1 rpm. The tablets are tumbled at each turn of

Fig. 1 Schematic of friability testing apparatus.

Tablet Testing

the drum by a curve projection with an inside radius of 75.5 mm–85.5 mm that extends from middle of the drum to outer wall. Thus, at each turn, the tablets roll or slide and fall onto the drum wall or onto each other. Usually, a sample of 10 tablets are tested at a time, unless tablet weight is 0.65 g or less, where 20 tablets are tested. After 100 turns, the tablet samples are evaluated by weighing. If the reduction in the total mass of the tablets is more than 1%, the tablets fail the friability test. Generally, the test is done once. If cracked, cleaved, or broken tablets are obvious, then the sample also fails the test.

Hardness Testing

A tablet requires a certain amount of mechanical strength to withstand the shocks of handling in its manufacturing, packing, shipping, and dispensing. As discussed before, hardness and friability are most common measures used to evaluate tablet strength. The need for testing hardness or crushing strength, in addition to friability, may be explained with an analogy that friability determines how fragile a tablet is. If a tablet is more fragile than expected, then the friability test will detect its substandard quality. However, on the other hand, if the tablets are more robust than desired, a friability test would not detect this deficiency. It is the tablet hardness test that will detect the deficiency.

The most widely used apparatus to measure tablet hardness is the Schleuniger apparatus. This, and other newer electrically operated test equipment, eliminates the operator variability inherent in the measurement using older apparatuses.^[5]

Generally, the force required to break a tablet may be expressed in either kilograms or pounds. It is of critical importance to note that because as results will vary with the specific make and type of the test apparatus used, direct comparison of results obtained on different types of apparatuses cannot be made. Thus, the same instrument must be used consistently throughout a particular study.

Disintegration Test

A disintegration test is a test to establish how fast a tablet disintegrates into aggregates and/or finer particles. The test assumes that if product disintegrates within a short period of time, such as within 5 min, then the drug would be released as expected and one should not anticipate a problem in the quality of a drug product. Although this test is in use for some products in pharmacopeias, its use is generally diminishing in favor of drug dissolution testing, which is described later in this article.

Fig. 2 Schematic of a tablet disintegration apparatus.

When required, the test is conducted using a specially designed instrument known as disintegration apparatus. A schematic representation of the apparatus is shown in Fig. 2. The apparatus employs a basket of six tubes with a base of metal sieve. A tablet is placed in each tube and is held in place by a plastic weight. The six-tube assembly, containing six tablets, is suspended using a hanger with a mechanism of vertical motion at a fixed speed. While hanging the six-tube assembly on the hanger, the assembly is moved in vertical motion in water or a buffer solution. The time for disintegration of each tablet is recorded and should meet the required time specification.

PHARMACEUTICAL AVAILABILITY

Checking the quality of drug products using chemical analyses, as described above, ensures that the product is of acceptable quality in its contents. However, this does not guarantee that the active ingredient in the product will be released in an acceptable manner. There are a number of factors, such as particle size, crystalline form, and compression during manufacturing that, individually or collectively, can severely impact the release of drug from a product thus affecting its efficacy. That is why drug release characteristics must be evaluated and established. The quality assurance around this concept represents one of the major components of product development and later

for quality assurance purposes. The gold standard to establish drug release characteristics of a product is based on an in vivo study, i.e., testing bioavailability (BA) of the drugs in humans.

Furthermore, in reality, changes in product formulation and manufacturing are anticipated and in many cases are unavoidable, for example, if there is a change in ingredient from the supplier, or change in a manufacturing component or facility itself. However, such changes create concern about the impact on the drug release profile and thus the safety and efficacy of the product. The only “gold standard” analytical test is to conduct a BA study to establish the similarity of the new product to the earlier (or the reference) version. However, conducting such BA studies is often one of the most expensive and time-consuming processes in the manufacturing of a product. In addition to the cost and time considerations, ethical concerns also limit the conduct of these studies in humans.

Thus, because of cost, time, and ethical considerations, it is not always possible to conduct drug release studies in humans, and an in vitro drug release evaluation test is the most desirable alternative. For this purpose, a dissolution test for tablet products has been developed and has become a tool for both product development and quality assurance. The test is conducted routinely at every stage of drug product development, during the manufacturing and postmanufacturing stages. A relatively detailed description of the concepts concerning pharmaceutical availability is presented here along with the issues and difficulties of the current approaches so that the reader may be aware of the directions of future development.

In Vivo Drug Release Assessment

To assess release characteristics, one would require to determine BA and/or bioequivalence (BE) characteristics of a product. Both BA and BE areas are subdisciplines of pharmacokinetic studies. Therefore, one would require to have some familiarity with the basic principle of pharmacokinetics. For the purpose of this article, the necessary pharmacokinetic concepts are described below. For further details see Refs. 6 and 7.

Bioavailability Studies

When a drug is absorbed from the gastrointestinal (GI) tract into the blood stream (systemic circulation), it is distributed throughout the body that results in reaching at the site(s) of its action. Concurrent to distribution, drug elimination from the blood due to metabolism or excretion to urine commences. Therefore, at any given time, drug

Fig. 3 Plasma drug concentration–time profile.

levels in the blood are the net result of this absorption and elimination processes. In the initial phase, the rate and extent of drug absorption is greater than that for the elimination; therefore, the absorption phase dominates, while at later times when all the drug is absorbed, it is the elimination process that dominates. Although exceptions exist, a typical observed blood drug concentration profile after dosing is shown in Fig. 3. From the analytical chemistry perspective, commonly it is not the blood, but the extracted plasma or serum that is analyzed and is used to reflect drug levels in blood.

The time to reach the maximum plasma drug concentration (C_{\max}) is termed as T_{\max} . The slope reflecting the increase of drug levels in the initial plasma drug profile represents rate of appearance/delivery of drug to the systemic circulation. Depending on the nature of the product, the rate of delivery could be critical. The slope reflecting the decrease of drug levels in the terminal phase of plasma drug concentration represents rate of elimination of drug from the systemic circulation. If one were to draw the curve shown in Fig. 3 on a semilogarithmic scale, i.e., time vs. $\log(\text{plasma drug concentration})$, then the terminal portion of the curve becomes a straight line, as the elimination rate is usually exponential. This rate of elimination is represented by a parameter k_e and is commonly known as elimination rate constant. These parameters, collectively or individually determine the rate of absorption/appearance of drug into systemic circulation.

Another important parameter is the area under the plasma concentration–time curve (AUC). It reflects the extent of drug absorption. From a product quality aspect, knowledge of the described pharmacokinetic parameters is important. Utilizing these parameters, one would establish drug release characteristics of a tablet in vivo.

Calculation of pharmacokinetic parameters

Obviously C_{\max} and T_{\max} are observational and determined directly from experimental results or the curve. Generally,

AUC is determined using the trapezoidal rule, as the arithmetic sum of average plasma concentration at two sampling times divided by the differences in sampling times, i.e., $(C_2 + C_1)/2(t_2 - t_1)$, up to the last measured plasma concentration. Such an area under the curve is termed as AUC_{0-t} . However, as the drug is still in the body and exponentially eliminated after the last determined concentration, the extent of drug remaining is determined by a formula $AUC_{t-\infty} = C_t/k_e$. Thus, the total $AUC_{Total} = AUC_{0-t} + AUC_{t-\infty}$.

To establish drug release characteristics of a product such as a tablet, one has to determine BA of the drug. Bioavailability is defined as a measure, relative to some standard, of the rate and amount of drug that reaches the systemic circulation. As C_{max} , T_{max} , and AUC are reflections of availability of drug in plasma, these parameters are used for determining BA of products. By comparing the derived pharmacokinetics from a BA study, similarity or dissimilarity of drug release in vivo is established.

The concept of BA is very critical from the drug quality perspective. Although, as stated above, chemical and physical tests are critical for testing the quality of tablet products, from the safety and efficacy perspective of drug products, it is the BA studies that are necessary. Even when content and quality of the tablets are within specifications, but release of drug in humans is not as expected, the substandard quality of the products could be dangerous to the health of its users. Therefore, BA studies are conducted at many stages of tablet product development and manufacturing, in particular, product development and receiving permit for marketing. A sample protocol for conducting BA studies for a tablet product testing is described below.^[8]

A comparative BA study is usually conducted in healthy humans, usually involving 12–30 volunteers depending upon the expected variability in the derived pharmacokinetic parameters. To minimize variability in derived parameters, the healthy volunteers should have certain characteristics such as age between 18 and 50 years, within normal weight range, and free from disease or any medication. The study protocol has to be approved by the institutional ethics committee.

Following an overnight fast, a dose is administered to the subjects with a controlled amount of fluid (250 ml of water). At a prescribed time, following the dose, a standardized meal is provided to each volunteer, again to standardize conditions so that results from any of the volunteers would not affect adversely.

Following the dosage administration, blood samples (10–15) are withdrawn from the volunteers. The idea behind selecting the sampling times is that one would be

able to accurately determine the C_{max} . Therefore, generally more frequent sampling times are needed at the lower part of the curve. Similarly, the terminal phase should have a sufficient number of sample times to establish the elimination rate constant. The duration of sampling should be such that most (at least 80%) of the drug, based on the area under the curve, should be accounted for.

The plasma samples are stored for later analysis. The samples are analyzed using validated analytical methods.^[9] The most commonly used methods are chromatographic, i.e., HPLC or gas chromatography. These methods, including the storage conditions, must be validated so that accurate and precise results are assured. Pharmacokinetic parameters from the plasma drug release profiles are determined for individual volunteers. The average values of these parameters reflect the BA of the product.

Bioequivalence Studies

A BE study is not as such an experimental study, but a form of reporting for a comparative BA study. In a BE study, a BA study is conducted to compare the results between reference and test products. A test product may be a product after a manufacturing or an ingredient change or a generic product. In fact, the whole generic industry is based on bringing products to the market based on conducting BE studies between innovators and their products. The study has to be conducted following a statistically valid approach and design, usually a crossover design, e.g., in one period, one-half of the volunteers are given one set of dosage form and in the second period, the order is reversed.

Once the experimental part of a comparative BA study is completed and respective pharmacokinetic parameters are derived and compared, the products are declared bioequivalent when they meet the set and expected specifications for the parameters. The requirements and parameters and their specifications may vary from country to country. However, the most common standard followed is that of the U.S. Food and Drug Administration (FDA). In this case, a 90% confidence interval of the ratios of the log-transformed values of parameters (C_{max} and AUC) should fall within the range 80–125.

Therefore, if one would like to establish impact of any change on pharmaceutical availability from a product or to develop a new formulation or product in comparison with an old product, these BA/BE studies remain the standard and are the requirements for showing the safety and efficacy of the altered/new product. However, from the routine quality control prospective as well establishing quality of a product after some minor changes in formulation or

manufacturing processes, the justification for BA/BE studies on economic and ethical reasons becomes difficult. Therefore, often only in vitro drug release testing is conducted. In the following sections, circumstances for the use of in vitro and in vivo methods are provided. However, a brief description of the current practice of dissolution testing is first given.

In Vitro Drug Release Assessment

Drug dissolution testing is a procedure used to evaluate drug release characteristics of solid oral products such as tablets. As in this article, it is also referred to synonymously as in vitro drug release assessment as opposed to in vivo drug release, which is commonly assessed in humans with studies using blood/plasma concentration profile information from BA or BE studies. The rationale behind conducting dissolution testing is that if a drug is to be absorbed from the GI tract, it usually has to dissolve. Therefore, for a drug to be absorbed, it has to be released from the product and dissolved in the GI fluid. Thus, a dissolution test is an established analytical test to assess the qualities of a drug product, based on its rate and extent of dissolution, i.e., release characteristics.

Commonly, dissolution tests are conducted with apparatuses comprising two major determinants that can be varied: 1) dissolution medium (nature and volume); and 2) a stirring and mixing mechanism.

Choice of dissolution media

As a dissolution test is conducted to simulate drug release in the human GI tract, the generally recommended media are based on aqueous buffers in the pH range of 1–8. Commonly used media are HCl (0.01–0.1 *N*) to simulate gastric fluid and phosphate or acetate buffer in the range of pH 4.0–6.8 to represent intestinal fluids. Recently, suggestions^[10,11] have also been made for other relevant dissolution media reflecting composition, volume, flow rates, and mixing patterns of the fluids in the GI tract. Volumes are usually in the range of 250 ml–1000 ml, however, the use of smaller and larger volumes are becoming common as well. A critical consideration in the choice of a dissolution medium volume is that drug should dissolve freely, i.e., without any concern of reaching saturation in the medium. In the case of low solubility drugs, solubilizing agents, such as sodium lauryl sulfate, are added to enhance the solubility. A low concentration of alcohol may be used to facilitate dissolution for low solubility drugs. However, larger concentrations of alcohol are to be avoided, as this might result in misleading or

unrepresentative results. The dissolution tests are conducted in media kept at a temperature of 37°C.

Stirring and mixing mechanism

The second major determinant for drug dissolution testing concerns the device for stirring or mixing of the product with the dissolution medium. The instrumentation for mixing, in effect the dissolution apparatuses, provides this aspect of the variant. Four different types of apparatuses based on different types of mixing approaches are available commercially and have compendial recognition. These apparatuses are known as: 1) paddle; 2) basket; 3) flow-through; and 4) reciprocating cylinder. For a detailed description and specifications of these apparatuses, readers should refer to any of the pharmacopeias such as the USP.^[12] A brief description of the apparatuses and stirring mechanism is given in the following sections.

Paddle Apparatus. In this case, the agitation is achieved by an inverted T-shape stirrer. The product is placed in the medium that is contained in a glass beaker with round-shaped bottom (Fig. 4). The stirring is achieved by rotating the spindle commonly between 50 rpm and 100 rpm. At specific times, samples are withdrawn and the percent of the drug dissolved is determined using any of the conventional analytical methods such as UV or liquid chromatography.

Basket Apparatus. This method is very similar to the one described above except that the inverted T-shape stirrer is replaced with a cylindrical metallic-wire basket (Fig. 4). The tablet product is placed in the basket that is attached to the spindle, which provides rotation to the basket. The dissolved drug comes out of the basket and mixes with the bulk medium. In this apparatus, it is possible that when the product is disintegrated and

Fig. 4 Schematic of USP drug dissolution apparatuses 1 (basket) and 2 (paddle). (From Qureshi, S.A. Calibration: The USP Dissolution Apparatus Suitability Test. *Drug Inf. J.* **1996**, 30, 1060, Fig. 2.)

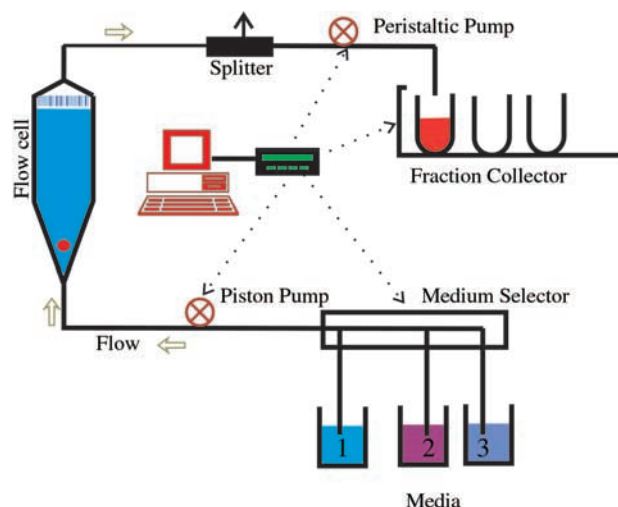

Tablet Testing

Fig. 5 Schematic of a flow-through drug dissolution testing apparatus, also referred to as apparatus 4 in the USP.

particles drop and settle at the bottom of the vessel without dissolving thus providing limited dissolution. Therefore, one may anticipate erratic dissolution results using such an apparatus, at least for some products.

Flow-Through Apparatus. In this type of apparatus (Fig. 5), no stirrer is present. The product is placed in the path of a flowing stream of dissolution medium. The dissolved drug is continuously removed and the exiting solution is measured for the dissolved drug. If required, the exiting liquid may be returned to the medium reservoir for recirculation, thus providing a closed-circuit operation with a limited or finite volume. However, its best use is achieved because of its open-ended operation with a large dissolution medium volume. The system is gaining popularity for products of low solubility drugs. Its main disadvantage compared to the paddle and basket apparatuses is that it is somewhat more challenging to operate.

Reciprocating Cylinder Apparatus. This system may be envisioned as a collection of tubes/vessels in series, as a set of six tubes. Each set of vessels contains a medium of similar or different characteristics such as pH. A hollow cylinder (Fig. 6) with a wire gauze base contains the product and moves in a vertical motion in each vessel. The dissolved drug is mixed with the external medium. At the end of preset time intervals, the vertical moving cylinder containing the remaining product is lifted and moved to the next set of vessels with fresh medium and the process is repeated a number of times. This instrument provides the strongest agitation. Aside from the advantage of the system that drug product can be tested at different pH values, the system appears to have significant

Fig. 6 Schematic of a USP 3 dissolution-testing apparatus, also referred to as reciprocating cylinder apparatus.

disadvantages. It provides limited volume; thus, solubility of drug can become an issue. There could be fluid carryover when the product in the vertical moving tube is transferred from one medium containing tube to the next. In addition, automation of such a system for unattended monitoring is not currently available.

Among the four apparatuses described above, most of the experimental work reported in literature is based on basket and paddle apparatuses.

Reporting Results and Tolerances

Generally, dissolution results are reported as cumulated percent drug release vs. time. Presently, most of the tolerances are based on a single time point, such as not less than 85% dissolved or released in 30 min. However, more reports are appearing with percent drug release values at multiple time points, resulting in a drug release pattern, commonly known as a “profile.”

Commonly, dissolution tests are conducted in a set of six units (tablets). Most commercially available apparatuses can run a test in a set of six units, thus resulting in saving of time and resources and leading to better reproducibility. Although tests are conducted in a set of six, generally results are reported for individual tablets. The most common form of tolerances is of the pharmacopeial ones such as the USP, which has been adopted by other pharmacopeias as well. These compendial standards are described in levels or stages, where each stage has its own set of tolerances that may be based on individual and mean results. For profiles, a similar approach of tolerances is followed while considering every sampling time point as a discrete set of results. It is important to note that there are no requirements and standards of variance around the mean such as standard deviation or coefficient of variation. A lack of such

standards for variation appears to be one challenge (weakness) in current dissolution testing practice.^[13,14]

Recently, a relatively new approach, known as pooled sampling, has also been adopted for reporting the results.^[15] This approach is based on reporting a single result obtained by pooling multiple samples, usually six. The advantages of this approach appear rather arguable. However, one significant disadvantage is that it would hide variability in results from tablet to tablet from a single lot or multiple lots, thus decreasing the quality of information obtained.

With regard to profiles, another parameter that has been introduced to compare drug release is (test vs. reference product) known as similarity factor or f_2 factor.^[16] In essence, it reflects a negative logarithmic sum of differences of percent drug release of two products over multiple sampling times. A value of this parameter in the range of 50–100 is considered to reflect similarity of profiles and thus similarity of products for drug release characteristics. However, there is limited information currently available in support of the usefulness of this approach.

Choice Between In Vivo and In Vitro Studies

Both of these types of studies are conducted to assess the drug release characteristics of tablet products. The gold standard remains in vivo studies. However, as stated earlier, it is not necessary, due to ethical and economical reasons, that one has to do the in vivo studies all the time. There are situations wherein the safety and efficacy aspect can be addressed by conducting only the in vitro studies.^[17,18] The confidence in the in vitro results as a reflection of in vivo results is obtained if an established in vivo–in vitro correlation (IVIVC) is available, i.e., in vivo drug release obtained from plasma drug concentration–time profiles reflects the observed drug dissolution characteristics. There are numerous ways of observing and reporting IVIVC.^[19–23] However, for the purpose of reliability, one generally compares the observed in vitro cumulative drug release results with the cumulative drug release in vivo derived from the pharmacokinetic data. Although there is significant enthusiasm in developing and reporting IVIVC in the scientific community, examples of successful IVIVC are rare for predicting in vivo characteristics based on in vitro results and vice versa. On the other hand, examples of lack of IVIVC may be found more frequently. For example, in a study^[24] to establish IVIVC, drug release characteristics of various primidone tablet products were assessed both in vitro (dissolution tests) and in vivo (BA/BE study). The results of the evaluation

indicate that even though there were large differences in the in vitro dissolution of the primidone tablets, the in vivo results were shown to be very similar.

In addition, one should also not expect an IVIVC for all drug products. The drug absorption into systemic circulation depends upon two aspects: 1) drug release in the GI tract and 2) permeability characteristics of the drug through GI tissue. If the absorption of a drug is permeability dependent, then one should not anticipate IVIVC because the IVIVC aspect only relates in vitro release to in vivo absorption or drug appearance in the body.

Based on the drug solubility and permeability characteristics, drugs may be divided into four groups: 1) high solubility–high permeability drugs; 2) low solubility–high permeability drugs; 3) high solubility–low permeability drugs; and 4) low solubility–low permeability drugs. This classification of drug into four groups is known as Biopharmaceutic Classifications System.^[25] Based on this classification system, one would anticipate a successful IVIVC with drugs in low solubility–high permeability group. In this type of drugs, as permeability is high thus as soon as drug is dissolved, one would anticipate corresponding absorption through the GI tissue. For the two categories that have drugs with low permeability values, because the drug absorption is permeability dependent, the IVIVC is unlikely to be observed. Furthermore, it is also unlikely that one would see IVIVC for drugs in the category 1, i.e., high solubility and high permeability category. The reason being that if a drug is fast dissolving, e.g., in less than 15 min, then one would anticipate saturation or overloading of the GI tract absorption system. Thus, changes in vivo dissolution would unlikely be reflected in plasma drug concentrations. However, if a high solubility–high permeability drug is formulated as a slow-release product, then the drug would appear as low solubility/dissolution drug and would behave as low-solubility–high permeability drug where IVIVC should be possible. Therefore, IVIVC is not only a drug-dependent characteristic; it is also a product-dependent characteristic.

Another reason for the lack of success of IVIVC may be due to the lack of relevant testing environment in vitro. The currently used methodologies not only offer very poor reproducibility of results, but also very poor mixing and stirring characteristics in vitro.^[14] Therefore, it is highly unlikely that general success of IVIVC could be achieved soon. There is a clear need for some improvement in this area.

Notwithstanding the above discussion, recently, there has been recognition of accepting in vitro results in lieu of in vivo results for the assessment of safety and efficacy of pharmaceutical products. Particularly, there has been

Tablet Testing

a guidance document^[26] from U.S. FDA that allows in vitro studies in lieu of in vivo studies. In this particular example, if a drug has high permeability and high solubility characteristics and no history of problem regarding the drug absorption, inference to safety and efficacy of the product after changes in product manufacturing can be granted provided if the products show equivalent in vitro drug release characteristics. The acceptance of in vitro results for in vivo is not based on IVIVC for this particular group of products, i.e., products with high solubility and permeability drugs and very fast in vitro release characteristics (more than 85% dissolved in 15 min), but because experience with such drugs is that these have no BA problems and are unlikely to cause a potential health risk.

In short, it can be said that BA/BE testing remains the gold standard for establishing the pharmaceutical ability of products in vivo. Due to ethical and economical reasons, BA/BE availability studies are mostly conducted at product development and major formulation and manufacturing process changes. However, an in vitro test, in conjunction with other analytical tests, is performed whether its relevance to in vivo is established or not that appears to provide adequate assurance of quality of products in particular anticipated release characteristics in vivo. Thus, drug dissolution testing has become an important and essential quality control test for establishing lot-to-lot consistency in the evaluation of products. Furthermore, in some cases such as for highly soluble and permeable drugs in fast release product characteristics, a dissolution test can also be used for a substitute of a BA study.

PRODUCT STABILITY EVALUATION

Product stability testing is an essential component of establishing the quality of the products. The stability parameters of a drug dosage form can be influenced by environmental conditions of storage (e.g., temperature, light, air, and humidity) as well as by the packaging styles.

Knowledge of the physical stability of a formulation is very important for two reasons. First, a pharmaceutical product must look fresh and elegant as long as it remains on the shelf. Second, the active ingredient must be available to the patient throughout the expected shelf life of the product. The causes of deterioration in quality of active ingredient could be due to incompatibility with excipients, oxidation, reduction, hydrolysis, and racemization to name a few.

With the exception of BA studies that are not conducted for the stability studies, all the above-mentioned tests are

Table 1 An example of commonly used protocol for stability testing of tablet products

Type	Conditions	Duration (mo)
Long-term testing	$25 \pm 2^\circ\text{C}/60\% \text{ RH} \pm 5\%$	12
Accelerated testing	$40 \pm 2^\circ\text{C}/75\% \text{ RH} \pm 6\%$	6
Alternate testing	$30 \pm 2^\circ\text{C}/60\% \text{ RH} \pm 5\%$	

Alternate testing is required if significant changes occur during 6 mo storage under conditions of accelerated testing.

performed after storing the product in the package material to declare that products of acceptable quality after the manufacturing. In vitro dissolution tests are relied on for the drug release characteristic in vivo. The analytical methods employed for stability testing must be validated to show that the accuracy and precision have not been effected by the interferences of any potential degradation product(s).

The stability studies on the active substances and packaged dosage forms are conducted by “real time.” Long-term tests at specific temperatures and humidity representing storage conditions experienced in the distribution chain of the climatic zone(s) of the country or region of the world concerned.

There are generally two types of stability studies conducted: 1) regular and 2) accelerated. In the case of accelerated stability study, the product is stored under elevated temperature and relative humidity (RH) conditions to force or expedite its degradation pathway and assess the changes. The stability testing conditions depend on the anticipated market environment. An example of a recommended protocol^[27] is provided in Table 1.

TARGETED DRUG DELIVERY: MONOCLONAL ANTIBODIES AS DRUG TARGETING AGENTS

Ban-An Khaw

Northeastern University, Boston, Massachusetts, U.S.A.

INTRODUCTION

The concept of targeted drug delivery may be considered to have originated with the proposed “magic bullet” of Paul Ehrlich for specific eradication of the spirochete of syphilis at the beginning of the 20th century (1). Yet this vision of targeted drug delivery did not begin until Pressman and Keighley in 1948 (2) demonstrated that radiolabeled antibodies could be specifically targeted to rat kidneys. Thus, antibodies became specific pharmaceuticals for targeting radioisotopes to various pathological disorders for diagnosis and therapy including various tumor. The next major thrust in the advancement of targeted drug delivery, using antibodies was provided by the revolutionary publication of Kohler and Milstein on monoclonal antibody technology (3). Monoclonal antibodies have since dominated the “targeting” in the targeted drug delivery systems.

The term targeted drug delivery conjures up a vision of a) a targeting moiety, and b) the drug to be targeted. The targeting moiety can be receptors, ligands, oligonucleotides, hormones, or antibodies. The drug to be targeted could be radioisotopes, pharmaceuticals, immunochemicals, chemicals, toxins, or biologicals. Thus, the concept of targeted drug delivery becomes almost all encompassing. Yet in practice, targeted drug delivery is somewhat restricted. Literature search of the term “targeted drug delivery” invariably resulted in the reference of articles relating to antibody mediated liposomes delivery system. Yet it should also include antibody, bispecific antibody, or avidin–biotin antibody delivery system. In oncology, antibodies may provide the primary targeting device for targeted drug delivery. Similarly antibodies form the primary targeting reagents in the cardiovascular applications. This chapter will restrict targeted drug delivery to targeting with antibodies and stress their applications in the cardiovascular arena, with cursory introductory review of the most pertinent targeting aspects in oncology.

ANTIBODIES IN CANCER IMAGING

Pressman and Keighley were the first to demonstrate that radioiodinated antibodies to normal rat kidneys targeted specifically to the kidneys in vivo (2). The potential for targeted delivery of radioisotopes for tumor therapy and diagnosis was immediately recognized by many investigators. However, progress for the next decade or so was disappointing due to lack of specific targets associated with tumors, pure antibodies for in vivo trials, and appropriate radiolabels for tagging the available antibodies. Never the less, Mach et al. (4), and Goldenberg et al. (5) succeeded in using polyclonal antibodies to carcinoembryonic antigen (CEA) to image carcinomas. Subsequently these same investigators used monoclonal antibodies to show that carcinomas can be imaged with radiolabeled anti-CEA antibodies (6, 7).

Since those early days of tumor imaging with immunoglobulin fractions, or affinity purified antibody fractions radiolabeled with I-131, monoclonal antibodies, and new and improved radiolabeling methods have enabled investigators to image breast (8), colon (9), lung (10), ovarian (11), and prostate cancers (12). Melanomas (13), T-cell lymphomas (14), pancreatic cancer (15), and indeed every form of cancer have been targeted with polyclonal or monoclonal antibodies in either experimental or clinical trials. Improvements in labeling with radioisotopes, such as Tc-99m, In-111, and I-123 to antibodies, have also led to better and more efficient gamma imaging. Further improvements in radioimmuno-cintigraphy include use of bispecific monoclonal antibodies (16) and multistep avidin–biotin conjugated antibodies to reduce nontarget organ activities and enhanced target to background ratios (17).

In the therapeutic arena, antibodies have also been used for immunotherapy and radioimmunotherapy. Immunotherapy itself is essentially targeted drug therapy where specific antibody may activate complement, attract inflammatory cells, and/or induce production of cytokines, or as in the case of Herceptin inhibit cell growth by

binding to ErbB2 that are overexpressed in metastatic breast cancer (18). Similarly, Rituxan is an antibody that binds to overexpressed CD20 in non-Hodgkins lymphoma (19) inducing apoptosis in these cancer cells (20). On the other hand, radioimmunotherapy may under certain oncologic conditions provide greater benefit. Use of murine–human chimeric monoclonal antibodies for targeting of ovarian cancer with β emitters for therapy has also been encouraging (21).

Immunotoxins consisting of tumor associated antigen specific antibody linked to the toxic chains of ricin, abrin, or other toxins have also been tested. Although phenomenal results in cancer therapy were anticipated, the progress has been disappointing. The only unequivocal success has been the *in vitro* treatment of bone marrow cells to rid them of malignant cells for subsequent injection into patients with hematological malignant cancer after whole body irradiation (22). Targeting of cancer cells with immunoconjugates of target specific antibody covalently linked with drugs, such as doxorubicin, have also been undertaken (23). Other methods for targeted drug delivery include use of immunoliposomes for delivery to specific tumors (24).

Despite these novel methods for targeted drug delivery directed with monoclonal antibodies, monoclonal antibodies have not totally met the expectations of the “magic bullet” of Paul Ehrlich in oncology. Therefore, apart from diagnostic imaging with radiolabeled monoclonal antibodies and direct immunotherapy, other innovative targeted drug delivery systems have had only limited clinical success.

TARGETED DRUG DELIVERY IN THE CARDIOVASCULAR SYSTEM

As indicated above, antibodies can provide target specificity as well as function as carriers of those drugs for targeted delivery. Whether the drug to be delivered is a radioisotope for imaging or therapy, or an antimetabolite, the prototypical model exemplified will be the radiolabeled antibodies for targeted drug delivery.

The application of antibodies in cardiovascular targeting *in vivo* originated with the experimental demonstration of the feasibility of using radiolabeled antimyosin antibody for diagnosis of acute myocardial infarction in 1976 (25). Since then, the use of antibodies in the cardiovascular system has encompassed imaging of myocarditis (26), heart transplant rejection (27), dilated cardiomyopathy (28), alcohol induced cardiomyopathy (29), adriamycin cardiotoxicity (30), various other cardiomyopathies (31), vascular clots (32), atherosclerotic lesions (33), and even

certain cancers such as soft tissue sarcomas (34). Yet the best characterized and studied antibody for cardiovascular diagnostic targeting is monoclonal antimyosin Fab for its exquisite specificity in the detection of myocardial cell death associated with various forms of cardiomyopathies.

Targeted Delivery of Radiolabeled Antimyosin Antibody in Acute Myocardial Infarction

To enable targeted delivery of any drug, there must be target specific structures not present on normal nontarget organs or cells that can be recognized by the targeting reagents, or neostructures must be exposed during the development of the pathological conditions. Since the cell membrane of normal cardiac cells are composed of the same lipid bilayer as that found in necrotic cells, one cannot envision a target specific cell membrane structure that is present only on the membranes of necrotic cells. However, it is reasonable to assume that structures such as the cardiac myofilaments are not exposed to the extracellular environment in viable cardiocyte, but following myocardial necrosis they would become exposed to the extracellular milieu (35). Therefore, such structures should provide new targets for delineation of the necrotic from nonnecrotic myocardium. Anticardiac myosin antibody was chosen as the model targeting moiety for the delivery of the model drug for diagnostic imaging of acute myocardial infarction (25). The above hypothesis was validated using hypoxic neonatal murine myocytes in primary cultures treated with antimyosin antibody attached covalently to 1 μ m diameter polystyrene beads, where the beads represented potential drugs for targeting (35). Normal myocytes with intact sarcolemma prevented accumulation of antimyosin beads (Fig. 1a) whereas hypoxic myocytes with sarcolemmal lesions were targeted by antimyosin beads at the lesions sites (Fig. 1b). Upon higher magnification ($\times 100,000$), targeting of the beads can be discerned as the myofilaments are seen wrapped around the antimyosin-beads (Fig. 1c). Such specific targeting of the necrotic myocardium can also be demonstrated *in vivo* in experimental and clinical situations by gamma imaging technology.

To establish without equivocation that antimyosin Fab can target the necrotic myocardium with highest specificity, a mixture antimyosin antibody labeled with I-125 and normal IgG labeled with I-131 was administered by intracoronary delivery into dogs with experimental acute myocardial infarction (36). Targeting of both radiolabeled immunoglobulin species was assessed by gamma scintillation counting (36). I-125 labeled antimyosin antibody localized in the necrotic myocardium with a target to nontarget ratio of $\approx 32:1$ at the infarct center, whereas

nonspecific localization was only about 6.5:1 in the same tissue samples (36). Similarly, in vivo demonstration of the specificity of antimitosin antibody for the necrotic myocardium was performed with antimitosin Fab (Fig. 2A) and nonspecific Fab radiolabeled with In-111 (Fig. 2B). Dogs with experimental acute myocardial infarction injected with In-111 labeled antimitosin Fab showed in vivo localization of the radiolabel conjugated to antimitosin Fab in the infarct. The nonspecific Fab control also radiolabeled with In-111 did not localize in the infarcted region of the myocardium in control infarcted dogs (37).

To further demonstrate the exquisite specificity of antimitosin for targeting acute myocardial infarction, two monoclonal antimitosin antibodies, one with high and the other with low affinity, were employed to visualize canine acute myocardial infarction. The low affinity antimitosin Fab (3H31E6) despite being specific for myosin, with an apparent affinity of $\approx 6.5 \times 10^6$ L/mole, showed no in vivo targeting of the radiolabeled antibody even at 5 h after antibody administration (Fig. 2D). On-the-other-hand, with the higher apparent affinity antimitosin Fab (R11D10) (1×10^9 L/mole), the infarct may be visualized as early as 1 hour but unequivocally some time later after intravenous administration (Fig. 2C) (37). The ratios of target (*T*) to blood pool (*B*) activities of the in vivo gamma images were determined by computer planimetry to be 1.7 ± 0.38 (mean \pm SD) for R11D10 Fab, which was significantly greater than that of 3H31E6 Fab (0.85 ± 0.12). The latter was the same as the *T/B* ratios obtained with nonspecific Fab (0.75–0.771) (37). Another monoclonal antimitosin Fab (2G42D7) with an apparent affinity similar to R11D10 also provided *T/B* ratio of 1.5 ± 0.27 ($p = 0.13$). These studies confirmed that not only is antimitosin specific for targeting acute myocardial necrosis, the requirement of sufficiently high affinity for successful in vivo visualization makes this targeting phenomenon exquisitely target specific.

Similarly, gamma images of patients with persistently occluded left anterior descending coronary artery (LAD) and another with reperfused LAD injected with In-111 labeled monoclonal antimitosin R11D10 Fab (38) showed

Fig. 1 Scanning electron micrographs of murine neonatal primary myocytes in culture treated with antimitosin linked 1 μ diameter fluorescent polystyrene beads. a) A normal myocyte showing the intact cell membrane and a lack of antimitosin-bead binding. b) A necrotic myocyte with a region of sarcolemmal disruption showing antimitosin-bead binding in that region. c) 100,000 times magnification of the region of cell membrane disruption showing antimitosin-beads wrapped around by the myofilaments that contain myosin.

Fig. 2 Gamma images of four dogs with acute experimental myocardial infarction, injected with high affinity ^{111}In -labeled antimyosin Fab ($K_a = 0.5\text{--}1 \times 10^9 \text{ L/M}$) (A and C), ^{111}In -labeled nonspecific monoclonal Fab (B) and the low affinity ^{111}In labeled 3H3 antimyosin Fab ($K_a = 5 \times 10^6 \text{ L/M}$) (D). At 5 h post intravenous administration of these antibodies, only the images with high affinity antimyosin showed unequivocal infarct uptake, whereas the images with nonantimyosin specific monoclonal Fab and the low affinity antimyosin Fab showed only blood pool activity. (From Ref. 37.)

unequivocal targeting of the radiopharmaceutical in the region of the hearts corresponding to the areas subtended by the occluded coronary vessels (Fig. 3). In patients with no infarction, no targeting of radioactivity in the myocardial region was obtained.

Despite the ability of antimyosin Fab to specifically delineate acute myocardial infarction, its utility is hampered by the slow blood clearance of the Fab fragments (38). This causes delayed development of high enough target to background ratios for in vivo visualization by gamma scintigraphy, especially in clinical use to $>12 \text{ h}$ after intravenous administration. Usually, images were acquired 18–24 h after IV administration, however, small MI may require 48 h of blood clearance to enable

unequivocal diagnosis. If on the other hand, qualitative diagnostic end-point is the desired outcome, irrespective of visual confirmation of the infarct size, then infarcts may be detected rather early after intravenous antibody administration over and above the blood pool activity (39). These rate-limiting steps may be overcome by using smaller antibody fragments, such as sFv (40), CDR (41), and mimetics (42). However, by increasing the clearance rate, there is a concomitant decrease in the absolute available antibody for target localization. Therefore, we developed a new approach to improve target to background ratios in experimental myocardial infarct visualization by decreasing the background activity without affecting the target activity at any time point.

Fig. 3 Anterior and 45° LAO images of two patient with acute MI at 24 and 26 h after intravenous administration of In-111 labeled antimyosin Fab. Images of a patient with persistently occluded LAD (no reperfusion) (top) and those of a patient with successful reperfusion (bottom). (From Ref. 38.)

ENHANCING IN VIVO TARGETED DRUG DELIVERY WITH NEGATIVE CHARGE-MODIFIED MONOCLONAL ANTIBODIES

Since antibodies are basic glycoproteins, under physiological conditions they are positively charged (43). Cells and extracellular matrices, on the other hand are negatively charged due to the presence of cell membrane bound acidic residues such as sialic acids (44,45) and heparan sulfate proteoglycans (46), respectively. Therefore, the potential for nonspecific ionic interaction between the positively charged molecules and the negatively charged cell surfaces or extracellular matrices exists. Such nonspecific interaction has been utilized to

deliver methotrexate–polylysine conjugates to malignant cells (47), protracted release of basic fibroblast growth factor for the salvage of the infarcted myocardium (46), as well as for the delivery of genetic constructs by lipofection or cationic liposomes (48). Alternatively, we proposed that if the basic (positively charged) antibodies were to be modified to carry a highly anionic polymer so that the isoelectric point of the modified antibody becomes low (e.g., $PI < 5$), then this modified antibody should have reduced nonspecific ionic interaction with nontarget cells and extracellular matrices (49). However, the affinity of the antibody at $\approx 1 \times 10^9$ L/mole can easily overcome the repulsive ionic forces when the charge-modified antibody approaches its homologous antigen. This would permit the same targeting of the charge-modified antibody as with the noncharge modified antibody due to the same antigenic specificity and affinity, but should result in lower nontarget background activity and thereby allow earlier development of high enough target to background ratios for visualization of the target (49). Furthermore, since negatively charged diethylene triamine pentaacetic acid chelate modified polymers are used, very high specific radioactivity radiolabeled antibody preparations can be prepared.

Antimyosin Fab was covalently modified with multi-DTPA conjugated polylysine that has been made totally anionic by succinylation (50). The immunoreactivity of the negatively-charge-modified AM-Fab carrying a polymer of approximate 3.3 or 17 kD was identical to that of the unmodified AM-Fab (50). When these negative charge-modified AM-Fab preparations were labeled with In-111, a specific radioactivity of 50–100 mCi/mg AM-Fab was obtained. The specific radioactivity of the conventional AM-Fab was only 2–10 mCi/mg AM-Fab. Thus, less negative charge-modified AM-Fab was needed to deliver the same radioactivity relative to the conventional dose. When the negative charge-modified AM-Fab was administered into dogs with reperfused experimental MI, myocardial infarcts were visualized within 30 min of intravenous administration of the antibody preparation (Fig. 4), whereas the conventional In-111 labeled AM-Fab required 1–2 h of antibody circulation and clearance before infarcts were visualized.

This earlier target visualization could be, as stated previously, due to quicker development of high target to background ratios for visualization by gamma imaging, which requires a ratio of about 10:1. It could also be due to a new concept developed in our laboratory where visualization could be achieved not based on target to background ratios, but on the absolute difference in the radioactivity between target and background (51). Assuming that the same amount (500 μ g) of charged

Fig. 4 Serial left lateral gamma images of two dogs with acute experimental myocardial infarction injected with negative charge-modified In-111 labeled antimyosin Fab (right panels) and conventionally In-111 labeled antimyosin Fab (left panels); a and b = 30 min images, c and d = 1h, e and f = 2h, and g and h = 3h post intravenous administration. (From Ref. 50.)

modified and unmodified antimyosin Fab radiolabeled with In-111, were injected into dogs with experimental MI, and at 5 h post injection there were $0.1718 \pm 0.0201\%ID/g$ (52) of negative-charge modified antimyosin Fab in the infarct, since the specific radioactivity of negative-charge modified antimyosin Fab was 100 mCi/mg, the absolute radioactivity in 1 g of infarct would be 85.9 μCi . On the other hand, 500 μg of unmodified antimyosin Fab with a specific radioactivity of

5 mCi/mg with $0.2041 \pm 0.0204\%ID/g$ would only have 5 $\mu Ci/g$ of the infarcted myocardium. Since normal myocardial activities were $0.0056 \pm 0.0004\%ID/g$ with charge-modified antimyosin Fab and $0.0263 \pm 0.0037\%ID/g$ with unmodified antimyosin Fab, the absolute background radioactivities were 2.8 and 0.658 μCi , respectively. Therefore, the difference between target and background for charge-modified antimyosin Fab would be 83.1 μCi and the ratio between

Fig. 5 Normal myocardial activity of polymer modified antimyosin Fab and conventionally In-111 labeled antimyosin Fab. (From Ref. 50.)

target to background would be 30.7:1. The difference in the absolute activity between target and background on the other hand for unmodified antimyosin Fab would be only 4.34 μCi and the ratio 7.6:1. Therefore, with a differential of 83 $\mu\text{Ci/g}$ between target to background, one should be able to clearly visualize the target quite early, whereas a differential of 4.34 μCi may not permit easy early visualization.

To determine whether earlier visualization was due to increased infarct activity or decreased nontarget organ activities, biodistribution data were also compared. Figure 5 shows that even in the normal myocardium (nontarget tissue), the radioactivity was significantly lower for 3.3 and 17 kD negative charge-modified polymer-AM-Fab than that of the conventionally labeled AM-Fab ($p < 0.001$) (50). The applicability of negative charge modification was further demonstrated in a rabbit model where an infarct as small as 216 mg was visualized by in vivo imaging within 3 h after intravenous administration (Fig. 6) (52). The percent injected dose localization in this animal was as high as 1.73% ID/g providing $\approx 86.3 \mu\text{Ci/g}$ of the target. The mean maximal target to nontarget (minimal) ratio from the seven rabbits was 53.9 ± 18.4 (52).

Therefore, negative charge modification of AM-Fab not only imparted lower nontarget organ activity without affecting the target activity, it also provided antibody preparations with very high specific radioactivity enabling the use of less proteinaceous compounds for in vivo administration. Furthermore, it also showed that when high target activity is achieved, visualization was possible earlier based on the difference between target and background activities, rather than target to background ratios. Whether this process of negative charge modification will ever find clinical application may not be determined by scientific feasibility but more by

Fig. 6 Left lateral gamma image of a rabbit with a 216 mg experimental myocardial infarct visualized with In-111 labeled negative charge-modified antimyosin Fab. Arrow points to the small infarct visualized in vivo. (From Ref. 52.)

commercial considerations. Nevertheless, a murine-human chimeric antibody F(ab')_2 specific for proliferating smooth muscle cells associated with atherosclerotic lesions has been negatively charge modified, labeled with In-111 and shown to localize in the carotid artery atherosclerotic lesions in all nine patients studied to date (53).

Antimyosin is highly specific and sensitive for diagnosis of myocardial necrosis associated with acute myocardial infarction. Despite its requirement of approximately 24 h lag time for unequivocal diagnostic imaging, it is highly useful for diagnosis of equivocal myocardial infarction, myocardial necrosis associated with unstable angina, right ventricular infarction (54), and perioperative myocardial infarction in by-pass surgery (55).

ANTIMYOSIN IMAGING IN DIAGNOSIS OF VARIOUS CARDIOMYOPATHIES

Myocarditis

Myocarditis is a cardiomyopathy of highly variable clinical manifestations that can in more severe cases, lead to dilated cardiomyopathy and heart failure (56).

It is believed to have a viral origin but the chronic component of the etiology is believed to be autoimmune in nature. To unify the diagnosis of the disease, the Dallas Criteria were formulated (57). The criteria mandated the presence of mononuclear cell infiltration and myonecrosis demonstrated in endomyocardial biopsies for unequivocal diagnosis of myocarditis. However, the criteria focused only at a limited phase of myocarditogenesis. Irrespective of the inflammatory obligatory component of the criteria, the presence of myonecrosis led us to propose that antimyosin immunoscintigraphy should be able to target the myonecrotic component of the disease and provide a very sensitive diagnostic indicator for noninvasive diagnosis of myocarditis. In the initial study of 28 patients with histories and clinical findings suggestive of myocarditis, In-111 antimyosin immunoscintigraphy was positive in 17 patients (61%) (Fig. 7, left panel) and negative in 11 (39%) (Fig. 7, right panel) (26). All antimyosin negative patients were also negative by endomyocardial biopsy criteria, whereas all biopsy positive patients were also positive by biopsy criteria (26). A potential complication in the use of In-111 antimyosin Fab for diagnosis of acute myocarditis is the misinterpretation of residual blood pool activity for myocardial uptake. Since myonecrosis associated with myocarditis is generally diffused and not as intense as seen in acute myocardial infarction, uptake of In-111 labeled antimyosin could also be diffused and of low contrast. Therefore, it is recommended that single photon emission tomographic imaging be performed in case of equivocation. The tomographic reconstruction images in the transverse, sagittal, and coronal views should show myocardial activities rather than blood pool activities.

Dilated Cardiomyopathy

It has been clinically suspected that active myocarditis is capable of resulting in heart failure and acute dilated cardiomyopathy. Although the exact number of cases of active myocarditis or ongoing inflammation that ultimately resulted in idiopathic cardiomyopathy is not known, Dec et al. (28) studied 74 patients (50 men and 24 women) with dilated cardiomyopathy with global ejection fraction less than 0.45 with In-111 antimyosin Fab. Thirty-nine patients (53%) were positive by imaging criteria. Of these 39, 11 patients had histologically verified myocarditis, whereas 28 showed no evidence of myocarditis on biopsy. Out of the remaining 35 patients with normal antimyosin images, 33 were also negative by endomyocardial biopsy criteria. However, two were false negative since they had biopsy verified myocarditis. Thus, the sensitivity of antimyosin imaging was 85% and the predictive value of a normal scan was 94%. However, the specificity was only 54%, using the Dallas Criteria as the gold standard. This low specificity is most probably due to the need to use a Gold Standard that is highly insensitive and because myocarditis is a disease of either right or left or both ventricles, and endomyocardial biopsies are primarily obtained from the right ventricles. Irrespective of this low specificity of antimyosin imaging for diagnosis of myocarditis, patients with abnormal antimyosin scan and biopsy results showed significant improvement in the mean ejection fraction from 0.27 ± 0.02 to 0.43 ± 0.04 within 6 months follow-up examination. Whereas, patients with normal scans and nondiagnostic biopsy results had only slight improvement in the ejection fraction from 0.19 ± 0.02 to 0.24 ± 0.03 . Furthermore,

Fig. 7 In-111 Antimyosin gamma images of two patients suspected of having myocarditis: a) positive image (left panel), and b) a negative image (right panel). The arrows point the myocardial activity.

Fig. 8 Planar anterior and LAO In-111 antimyosin gamma images of a patient with biopsy positivity for myocarditis obtained initially when the left ventricular ejection fraction was only 34% (left panels) and after 6 months of steroid therapy (right panels) when the LVEF had normalized to 55% are shown.

those patients with positive antimyosin scans and negative biopsy results showed significant improvement in ejection fraction at follow-up indicating that since spontaneous improvement in cardiac function is a recognized feature of active myocarditis, the subset of patients with antimyosin scan positivity and spontaneous improvement in the cardiac function had myocarditis, which biopsy failed to detect. Negative antimyosin imaging can also be used to follow efficacy of therapy. Fig. 8 shows that although the initial antimyosin images were positive, after 6 months of steroid therapy, the images were negative for myonecrosis component of the Dallas Criteria.

Heart Transplant Rejection

Since commencement of immunosuppressive treatments for acute heart transplant rejection is predicated on the presence of myonecrosis on endomyocardial biopsies, antimyosin imaging should also be applicable for directing therapy. Frist et al. (58) showed that antimyosin could be used to detect myonecrosis associated with acute rejection. However, they also noted that immediately after transplantation, there appeared to be a basal uptake of In-111 labeled antimyosin Fab probably due to myocardial injury associated with transplantation related procedures. Subsequently Ballester et al. showed systematically that this initial antimyosin positivity could return to baseline as quickly as 3 months after transplantation (59). Furthermore, they showed that if antimyosin uptake assessed as Heart to Lung activity ratios remained elevated for greater than 1 year after transplantation, prognosis for the patient was poor and that patient was

a prime candidate for re-transplantation. Various degrees of intensity of In-111 antimyosin uptake were shown in Fig. 9, ranging from normal antimyosin scan (A), to mild uptake (B), to moderate uptake (C), to significant uptake (D) (60).

Antimyosin imaging appears to be highly sensitive for the detection of acute heart transplant rejection. Relative to the gold standard of endomyocardial biopsy, antimyosin has a sensitivity of 95% (61), however, specificity was only 33%. This discrepancy may be due to a lack of specificity of antimyosin or to a low sensitivity of biopsy in the detection of rejection. However, sampling error of endomyocardial biopsy is a distinct possibility that may account for the discrepancy since transplant rejection is histologically a patchy process. Therefore, if antimyosin were taken as the gold standard, then the sensitivity and specificity of endomyocardial biopsy would be 31 and 95%, respectively (61). This is consistent with the low diagnostic yield of endomyocardial biopsy reported for the diagnosis of active myocarditis (62, 63)

Other Cardiomyopathies

Due to the mechanism of targeting of antimyosin Fab, it appears that antimyosin could also be used to delineate various cardiomyopathies as long as there is an association of the disease process with irreversible myocardial injury where the integrity of the cell membrane has been compromised. Therefore, antimyosin Fab has been used successfully to demonstrate myocardial injury due to Adriamycin cardiotoxicity (64), in Rheumatic carditis (65), in Lyme carditis (66), Churg–Strauss disease (67) and Cardiac contusion (68).

TARGETING VASCULAR DISORDERS WITH RADIOLABELED ANTIBODIES

Imaging Blood Clots

Attempts to image blood clots preceded the era of monoclonal antibodies. Spar et al. used polyclonal antifibrinogen antibodies to detect thrombi in vivo in the mid 1960s (69). Since the antibody reacted with fibrinogen as well as fibrin, the specificity for the detection of preformed clots was poor. Hui et al. in 1983 (70) developed monoclonal antibodies (59D8 and 64C5) specific for the β chain of the fibrin molecule. They were made to a 7 amino acid *N*-terminal sequence of the β chain of fibrin. Since the *N*-terminus of the β chain of fibrin constitutes neoantigen generated when fibrinogen is cleaved by thrombin, these monoclonal antibodies did not cross react with fibrinogen. Kudryk et al. (71) also generated a similar monoclonal antifibrin T2G1S that

also reacted with the same *N*-terminal of the β chain of fibrin. Although there are other monoclonal antibodies with varying specificities for fibrin, only 59D8 and T2G1S have seen clinical studies. Fig. 10 (left panel) shows a 24-h-image of the lower extremities of a normal subject, whereas Fig. 10 (right panel) shows a set of spot images in a patient with venographically documented DVT.

It appears that imaging DVT was quite easily feasible in experimental and clinical trials. Whether imaging of pulmonary emboli in a clinical situation with monoclonal antifibrin antibody would be successful is not known. Experimentally, Kanke et al. (72) showed that 64C5 monoclonal antifibrin was able to image PE. However, small PE of <50 mg were not visualized in vivo by gamma imaging despite a correlation between clot size and total antifibrin uptake. Further improvements are needed to make this method of detection of DVT or PE a clinical reality.

Fig. 10 Anterior gamma images of normal control (left) and patient with DVT (right) with Tc-99m labeled antifibrin Fab. Radiolabeled antifibrin uptake can be seen in the left thigh and calf regions. (From Ref. 32.)

Targeting Atherosclerotic Lesions with Radiolabeled Antibodies

Atherosclerosis is another intravascular pathological disorder that appears to be amenable to targeting with monoclonal antibodies. It was initially thought that atherosclerotic lesions possessed no unique compounds that could serve as specific targets. These lesions are composed of macrophages that had become foam cells by the ingestion of oxidized LDL, and smooth muscle cells of the synthetic phenotype. No differentiated antigens were thought to exist in the lesions. Therefore, conventional modes of diagnosis, such as arteriography or ultrasonography, were believed to suffice for providing information on the anatomical narrowing of the affected vessels. Although these methods are effective, they cannot provide pathophysiologic information that may shed light on the stability as well as the pathogenesis of the lesions.

To elucidate the potential metabolic component of the pathogenesis of atherosclerotic lesions, several approaches have been taken experimentally. Radiolabeled oxidized LDL (73) as well as antibodies to the activated macrophages (74) have been tried with some

results. A monoclonal antibody that is specific for a complex antigen produced only by the proliferating smooth muscle cells of atherosclerotic lesions was developed by Scotgen Biopharmaceuticals, Inc. (75). This IgM isotype antibody designated Z2D3 (76) was shown to be able to target experimental atherosclerotic lesions in a rabbit model (77). The IgM subclass of Z2D3 was class switched to IgG as well as genetically engineered to produce a murine-human chimeric IgG Z2D3 antibody. Fig. 11 (top panel) shows a set of gamma images of a rabbit with experimental atherosclerotic lesions targeted with In-111 labeled chimeric Z2D3 F(ab')₂. The lesions could be visualized in the region of the descending aorta that was the site of experimentally induced lesions. In this model, the lesions were induced by de-endothelialization of the descending aorta from the region of the diaphragm to the bifurcation of the femoral arteries (75). The rabbits were kept on 6% peanut oil, 2% cholesterol enriched chow for at least 3 months. This protocol produced lesions that are more akin to human fibrous lesions, unlike the fatty streak lesions observed in Watanabi hyperlipidemic rabbits. As controls, rabbits with similar lesions were injected with In-111 labeled charge-modified normal human IgG F(ab')₂ (Fig. 11, lower panels). No specific targeting was seen in vivo in

Fig. 11 Left lateral oblique images of rabbits with experimental atherosclerotic lesions induced in the descending aorta imaged with In-111 labeled murine-human chimeric Z2D3 F(ab')₂ (Top panels) and In-111 labeled human IgG F(ab')₂ (Bottom panels). The in vivo gamma images are shown in the left panels (k = kidney, U = urinary bladder activity, solid thin arrows = atherosclerotic lesions, and open larger arrow = spinal activity), and the ex vivo images of the excised aortas from the aortic arch to the femoral bifurcation are shown in the right panels.

the region of the experimental lesions. Immunohistologically, this antibody stains the region of smooth muscle cell proliferation and not the quiescent smooth

muscles of the contractile phenotype of the media (Fig. 12). Ultimately, the negative charge-modified chimeric Z2D3 F(ab')₂ was used to determine whether

Fig. 12 Immunoperoxidase staining of frozen sections of atherosclerotic rabbit descending aorta (left panel) and normal rabbit aorta (right panel).

it could delineate atherosclerotic lesions in carotid lesions in patients (78). Using planar and SPECT imaging, it was observed that the lesions were better

detected with SPECT imaging (Fig. 13) (79). Whether this antibody Z2D3 will have wide clinical application must await additional trials.

Carotid Angiogram

Z2D3, Coronal

Fig. 13 Coronal tomographic image of a patient with carotid atherosclerotic lesions obtained 4 h after IV administration of In-111 labeled negative-charge modified murine-human chimeric Z2D3 F(ab')₂ (right panel). The arrow denotes the carotid lesion. The acrotid angiogram demonstrating a severe right internal carotid artery lesion (arrow) is shown in the left panel).

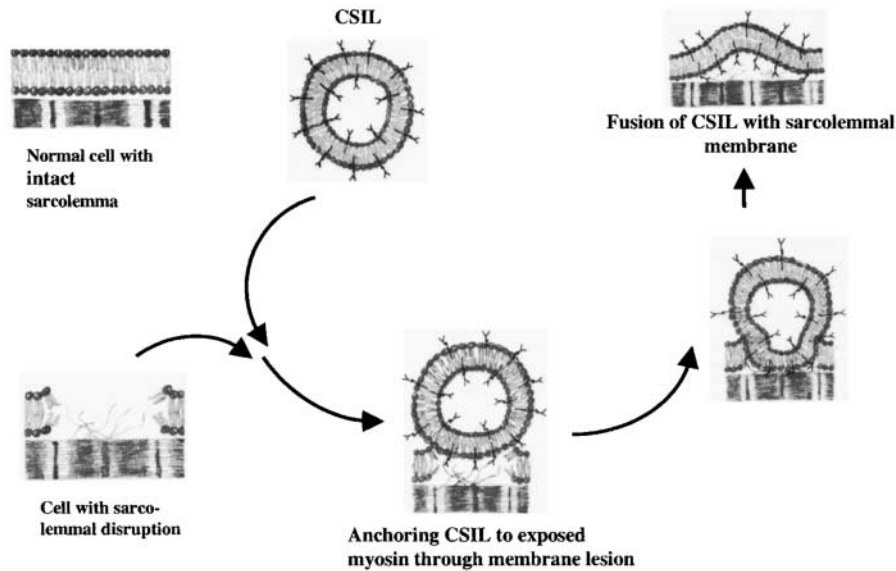

Fig. 14 Diagrammatic representation of the hypothesized mechanism of cell membrane sealing and salvage by antimyosin liposomes. (Adapted From Ref. 84.)

TARGETING CELL MEMBRANE LESION WITH CYTOSKELETAL-ANTIGEN SPECIFIC IMMUNOLIPOSOMES

Two primary kinds of cell deaths are now known to exist in the animal kingdom. Oncotic (formerly known as necrotic) and apoptotic cell deaths differ in that the former is due to external nonphysiological injury to the cell (80) and the latter "apoptosis is due to internally mandated process of suicide cell attrition or programmed cell death known" (81). Under pathological conditions of an ischemic insult to organs, such as the heart and the brain, the primary mode of cell death in the center of infarction is oncotic (82). Apoptosis plays a role in the periphery and in reperfused regions (83). Acute myocardial infarction is believed to be the result of oncosis, where development of cell membrane lesions constitute the irreversible phase. The presence of these lesions, which is initially represented by sub-microscopic holes in the sarcolemma in the acute phase of myocardial injury, permits washout of intracellular macromolecules into the circulation. At the same time, certain intracellular proteins including the components of the cytoskeleton, such as myosin and vimentin, become exposed through these holes to the surroundings milieu. Appropriately labeled antibodies against intracellular cytoskeletal antigens have been used to demarcate these cell membrane lesions (25).

Therefore, we hypothesized that if these cell membrane lesions could be sealed at the time or prior to reperfusion, then viability of myocardial cells should be preserved (84). To achieve cell membrane lesion sealing, we proposed that liposomes would be the ideal agent. However, the liposomes must be provided with target recognition sites that are specific for the lesions in the cell membrane. To achieve this, a monoclonal antibody that specifically recognizes myosin of the myofilaments that constitutes the cytoskeleton of the muscle cells was used. Thus, antimyosin immunoliposomes should be able to target the cytoskeletal myosin exposed through the small lesions of the cell membrane during the process of ischemic injury before the lesions become too large for repair (Fig. 14).

Preservation of Cell Viability by Cytoskeleton-specific Immunoliposomes

Proof of concept studies were performed in vitro in cell cultures of H9C2 rat embryonic cardiocytes. Two million H9C2 cardiocytes were incubated in aliquots of 10% fetal calf serum in DMEM at 37°C, 5% CO₂. After overnight incubation, the cells were washed in phosphate-buffered saline and recultured in fresh medium (with or without different liposome preparations) (84). Nitrogen was bubbled through the medium vigorously for 4 min dislodging all cells (>95%) from the bottom of the flasks. The flasks were then closed tightly to maintain hypoxia

Fig. 15 Comparison of cell viability of H9C2 cardiocytes in culture by Trypan Blue dye uptake criteria. Viability of hypoxic (24 h) cells treated the IL were compared to PL or IgG-liposome. Positive control was the normoxic cultures and the negative control was hypoxic cells with no treatment. (From Ref. 84.)

Fig. 16 Comparison of cell viability of H9C2 cardiocytes by ³H-Thymidine uptake criteria. Viability of hypoxic cells (24 h) treated with IL was compared to Normoxic cells ($p = \text{NS}$), PL treated hypoxic cells ($p < 0.01$) and untreated hypoxic cells ($p < 0.01$). (From Ref. 84.)

through overnight incubation at 37°C. H9C2 cardiocytes in hypoxic culture conditions were incubated with anti-myosin-immunoliposomes (IL), plain liposomes (PL) and control nonspecific IgG liposomes (IgL). Hypoxic and normoxic cardiocytes without liposome treatment were included as additional controls. Liposomes were prepared from a mixture of egg phosphatidylcholine and cholesterol at a molar ratio of 7:3. For incorporation of antimyosin antibody 2G42D7 into liposomes, the antibody was modified with N-glutaryl phosphatidyl ethanolamine (NGPE) (85,86) and added to the detergent-solubilized lipids. Liposome preparations containing fluorescent rhodamin-labeled lipids were also used for fluorescent microscopy and confocal microscopy (84).

At the end of the hypoxic period, viability of the cells were assessed by the Trypan Blue dye exclusion criteria. Fig. 15 demonstrated that the viability of hypoxic cells treated with IL were not significantly different from the viability of the normoxically cultured H9C2 cardiocytes. The viability of hypoxic cardiocytes treated with plain liposomes or IgG-liposomes was significantly lower than either those of immunoliposome treated hypoxic cells or normoxic cells. Since there was no difference in viability in cardiocytes treated with PL or IgG-liposomes, subsequent studies utilized only PL treatment as control. The phenomenon of preservation of cell viability with IL treatment was reaffirmed by ³H-thymidine uptake studies (84). DNA replication as reflected by ³H-thymidine uptake, was similar in the normoxic cells and the hypoxic cells treated with IL. However, cells treated with PL had only about 10% of ³H-thymidine

uptake of either the normoxic or IL treated hypoxic cells. Hypoxic cells with no treatment at all showed almost no

Fig. 17 Epifluorescent micrographs of 24 h hypoxic H9C2 cardiocytes treated with rhodamine labeled IL (right) or rhodamine labeled PL (left). Cells treated with IL were all viable; however, they all showed attached rhodamine fluorescent indicating attachment of IL to the cells. (From Ref. 84.)

^3H -thymidine uptake, indicative of a lack of viable cells (Fig. 16).

The sites of targeting of IL on hypoxic cardiocytes was visualized by fluorescent microscopy, using rhodamine labeled antimyosin immunoliposomes. Fig. 17 shows that only cells treated with antimyosin–rhodamine labeled IL were still confluent in the culture and that almost all cells were labeled with fluorescent liposomes. Those cells treated with rhodamine labeled PL showed extremely sparse number of cells still attached to the culture plates at 24 h of incubation, with essentially no or minimal fluorescence. Confocal microscopic examination of the cultures treated with rhodamine labeled IL showed that the cells still retained their morphology and shape with scattered fluorescent liposomes attached to the cell membranes (Fig. 18, left panel). Those cells treated with rhodamine labeled PL were shrunken and only a few random cells showed some nonspecific attachment of fluorescent PL (Fig. 18, right panel). In this study, untreated hypoxic cells were all dead and since there was no fluorescent compounds added in them, no micrographs were obtained.

It is also very important, how efficacious this protective effect can last. Therefore, we undertook a study to determine whether antimyosin IL can protect severely injured cardiocytes cultured under hypoxic conditions for 1–5 days (87). The experiment was designed as already described, however, cells were kept under hypoxic conditions during different times. Cell viability was assessed by ^3H -Thymidine (^3H -T) uptake. Untreated hypoxic cardiocytes (HC), normoxic cardiocytes (NC), and cardiocytes treated with PL were used as controls. Survival of NC increased from 100% (the mean ^3H -T uptake in control NC was assigned 100%) to ca. 250%

after 24 h indicative of cell replication, whereas virtually no cardiocytes survived after 24 h of hypoxia. PL added to HC provided some protection. Cell viability after 24 h was ca. 78%, which dropped to ca. 4% after 2 days of hypoxia, and to less than 1% after 3 or more days. However, when hypoxic cells were treated with IL, not only did IL conferred protection, IL also permitted cell replication. This is evidenced by the similarity in the increase of ^3H T uptake after 24 h in NC (250%) and in IL-treated HC (ca. 225%, $p = \text{NS}$). These data show that the protective effect imparted by IL on hypoxic cells leads to a long-term preservation of cardiocyte viability that might be especially apropos for preservation of cell viability during organ transportation for transplantation.

Preliminary In Vivo Experiments on Decreasing Infarct Size with CSIL

In our preliminary study utilizing a model of myocardial infarction in rabbits, when antimyosin IL, IgG-L, PL, or saline placebo were delivered concomitant with circumflex coronary artery occlusion for 45 min followed by reperfusion, the infarct size determined at 6 h of reperfusion, of IL treated rabbit hearts were approximately 5–10% of the control PL, IgG-L, or saline placebo treated rabbit hearts (88). Fig. 19 shows nitroblue tetrazolium stained heart sections of IL treated rabbit (top left panel) relative to PL (top right panel), IgG-L (bottom left panel), or saline placebo (bottom right panel) treated rabbit hearts. In nitroblue tetrazolium staining, normal myocardium stained as purple to dark brown, where as the infarcted myocardium is seen as light colored regions. Whether intravenously delivered IL would have any efficacy

Fig. 18 Confocal micrographs of 24 h hypoxic H9C2 cardiocytes treated with rhodamine labeled IL (right) or rhodamine labeled PL (left). The micrographs are shown in pseudocolors. Cells treated with IL showed retention of membrane integrity and cell morphology (left panel). Liposomes represented as yellow colored regions are also discernable on the cells. Cells treated with PL showed presence of only dead cells with only a few cells having nonspecifically attached PL (right panel). (From Ref. 84.)

Fig. 19 Nitroblue tetrazolium stained heart sections of rabbits with acute myocardial infarction treated with PL (left panel), saline placebo (middle panel) and IL (right panel). The sites of left circumflex coronary artery occlusion can be seen in the middle and right panels to be at the 4th slices by the presence of the silk sutures. Normal myocardium is stained purple or brown, whereas the infarcted regions remain as light colored regions.

relative to direct intraatrial delivery of the liposomes is not known at this time. None the less, in acute myocardial infarction, angioplasty is an alternative method to thrombolytic reperfusion therapy, therefore, in combination with angioplasty, it may be possible to deliver the IL directly into the infarct zone at the time of angioplasty.

Fusion of Cytoskeleton-specific Immunoliposomes with Hypoxic Cells

To demonstrate that preservation of cell viability is due to fusion of IL with the cell membranes, IL were prepared with intraliposomal silver grains. The rationale was that the only way silver grains can enter the treated hypoxic cardiocytes is by fusion of the IL with the cell membrane that resulted in preservation of cardiocyte viability. If endocytosis of the IL is the process of internalization without fusion, then plain liposomes should also show internalization of the silver grains. To prepare such liposomes (84), silver nitrate was added in a buffer solution during liposome preparation by sonication.

Liposomes, purified from the nonentrapped silver nitrate by dialysis were dialyzed in 0.12 M NaCl solution and exposed to light for 1 h that led to the formation of fine electron-dense precipitate of silver oxide inside liposomes.

Figure 20 shows that only cells treated with silver grains impregnated antimyosin IL retained the cell morphology and showed internalization of the silver grains (Fig. 20, top panel). Cardiocytes treated with silver grains impregnated PL showed no viable cells. However, after extensive search one viable cell was identified. The silver grains were observed outside the cell (Fig. 20, bottom panel) (89). The size of each clump of silver grains seen in Fig. 20 top panel is consistent with the size of the liposomes that were prepared and was approximately 200–300 μm in diameter. From this study, it was not possible to determine whether silver grains would also migrate to the nucleus. Silver grains, once internalized may not be as mobile as soluble pharmaceuticals or genetic constructs. Furthermore, since no internalization of silver grains was observed with PL, the mechanism of internalization seen with IL does not appear to be due to endocytosis or pinocytosis. Therefore,

Fig. 20 Transmission electronmicrographs of hypoxic H9C2 cardiocytes treated with silver grains impregnated IL or PL. Silver grains in seen intracellularly in IL treated cells; arrows, arrow heads represents 1 μ m. (From Ref. 84.)

internalization of the silver grains delivered by IL is consistent with the proposal that cytoskeleton-specific IL is able to fuse with the membrane of hypoxic cells releasing their contents into the cytoplasm.

Intracytoplasmic DNA Delivery

Since antimyosin immunoliposomes can be used to seal cell membrane lesions (84) and intraliposomally entrapped silver grains can be delivered directly into the cytoplasm (88), we also hypothesize that if we substitute genetic constructs for the silver grains, then such constructs should

also be deliverable directly into the cytosol (90). Delivery of genetic constructs directly into the cytosol, bypassing the endocytic route, might result in higher efficiency of gene expression. To demonstrate this hypothesis, we initially used antimyosin sFc vector (90), then pGL2 luciferase vector (91) and finally bacterial beta galactosidase vector (92). The rationale for using three different vectors is to show that irrespective of the origin of the vectors, one murine, one insect, and one bacteria origin, they all can transfect the cardiocytes and result in very efficient gene expression. All these in vitro studies showed that vectors delivered directly into the cytoplasm were

Fig. 21 Evidence of successful gene transfection with bacterial β -galactosidase vectors with IL in hypoxic cells, or with cationic liposomes or IgG-liposomes. The β -galactosidase activity was developed with X-Gal at pH 7.0. Cells treated with IL- β -galactosidase vector showed many cells with blue color. The culture was also confluent. Cells treated with cationic liposome- β -galactosidase vector showed only two cells with gene expression. The cells were also not confluent indicating cell attrition. IgG-liposome treated cells also showed no β -galactosidase expression.

expressed with very high efficiency. Comparative studies with standard cationic liposomes showed that although transfection efficiency of cationic liposomes was very efficient, due to the over-loading of the cell membrane with approximately 40,000 liposomes per cell (93), the viability of transfected cells declined dramatically. Furthermore, since internalization of the vectors is via endosomes, the factor of vector loss due to lysosomal activity was considerable as evidence by a lower number of cells expressing the gene products.

When IL was used for transfection of bacterial β -gal vector into hypoxic cells, the majority of the cells showed bacterial β -galactosidase activity when stained with X-gal color reagent. Although individual cells transfected with IL displayed less β -galactosidase activity than those few cells expressing the enzyme activity after cationic liposome transfection, the total number of cells demonstrating gene expression were at least 40 times more (94). This result is consistent with our calculation that only 3–4 copies of vectors were delivered per cell by IL transfection, whereas when cationic liposomes were used, more than 3000 copies of the vectors were delivered per cell (94). Fig. 21 shows the comparison of the photomicrographs of cells with successful expression of the β -galactosidase vector transfected with IL (A) or cationic liposomes (B) and IgG liposomes (C). Those cells treated with PL similar to IgG-L also showed no transfection.

Although the present novel method of gene transfection requires institution of an insult to the cell membrane, our studies with cell viability already showed that almost no cells were lost due to cell death in these treated cultures. Therefore, for efficient *in vitro* cell transfection and gene expression, this immunoliposome method would be highly desirable. Whether this method would be valuable *in vivo*, additional studies are necessary.

CONCLUSIONS

Monoclonal antibodies are the targeting moieties of the “targeted drug delivery systems.” Whether the drugs to be targeted are radioisotopes for diagnosis or therapy, or chemotherapeutic agents such as doxorubicin that are directly attached to the antibodies as immunoconjugates or entrapped in liposomes and targeted as immunoliposomes, the antibodies provide the most easily available and versatile targeting reagent. Although this article has concentrated on the demonstration of antibodies in targeted drug delivery in the cardiovascular system, their potential is by no means restricted to this system. The imaging and therapeutic applications described for the cardiovascular system should be amenable to adaptation to other organ systems. A cursory discussion

of monoclonal antibodies in oncological uses was provided. Although the potential targeted drug delivery applications in neurological and other systems were not discussed in this article, their utilities are by no means negligible. However, it would be the subject of another article. Therefore, only the cardiovascular application of monoclonal antibodies in targeted drug delivery has been attempted in this review.

TECHNOLOGY TRANSFER CONSIDERATIONS FOR PHARMACEUTICALS^a

Ira R. Berry

Duramed Pharmaceuticals, Inc., Somerset, New Jersey, U.S.A.

INTRODUCTION

Technology transfer for pharmaceutical products is a program that has been followed for some time (1–11). Issues to be considered when organizing the transfer of technology from the research arena to the production and quality assurance environments are reviewed in this article. The discussion focuses on the coordination and implementation of a transfer program for a product, with emphasis given to those factors special to the pharmaceutical industry. The success of any program is highly dependent on the effectiveness of the communication preceding its implementation; therefore, the preparation and distribution of a complete document summarizing raw material and equipment requirements, manufacturing and packaging processes, process validation parameters, quality control procedures, and safe handling procedures—as well as a detailed plan of action outlining expected results and time frames—must be distributed before the scale-up experience. Input from the marketing and manufacturing centers must be integrated into the plan to ensure that the right product is developed at the right price within the desired time frame. An outline encompassing these critical aspects of a transfer program is presented.

Whether a tablet, a transdermal patch, a topical ointment, or an injectable, the transformation of a pharmaceutical prototype into a successful product requires the cooperation of many individuals. To complete the task efficiently, the transfer of a product from the research and development area to production must be organized. Planning for process commercialization is one area where tangible rewards can be realized. The successful transfer of a project to a production site from the research arena does not happen on its own. Organizing the transfer of a technology or new product from research to production may be one of the most perplexing problems that development scientists, engineers, and marketers may encounter during their careers. This article provides some

insight into the issues that should be considered during the transfer program and offers a sequence of events toward completing the task.

A major decision focuses on that point where the idea or process is advanced from a research-oriented program to one targeted toward commercialization. Generally, the cost of product development rises dramatically during the pilot scale-up and initial production batch efforts. In other words, the critical path for success is dependent on the completion of the technology transfer to the production site at an affordable cost.

The three primary considerations to be addressed during an effective technology transfer are the plan, the persons involved, and the process. A plan must be devised to organize the personnel and the process steps. Once prepared, the plan must be communicated to the involved parties in research, at the corporate level, and at the production site. The success of any program is highly dependent on the effectiveness of the communication preceding its implementation. Therefore, identifying the parties involved in the development process is one of the most important tasks to be confronted and must be completed early in the transfer process.

PERSONNEL

The proper personnel must be informed of their involvement, desired contributions, and responsibilities. This helps identify potential problem areas that may hinder the accomplishment of the challenge at hand. It is desirable to appoint a project leader or liaison from the research and development group as the focus of the communication pattern. This individual has the responsibility to coordinate the assembly of the necessary information to support the product's advancement for process development. The trap to avoid here is to assign someone to this role and not give him or her the authority commensurate with the responsibilities with which he or she has been charged. The practice of pairing a seasoned project manager as a mentor with a less-experienced future

^a(Revised from Ref. 1.)

project coordinator is recommended. In this manner, team players can be nurtured. The communication and networking skills of the successful manager can be shared across the organization. On the other hand, it is expected that individuals who do not possess the necessary talents to be effective are identified before they encounter the stressful world of project management alone and, more importantly, before they have a chance to contribute to the failure of a potentially successful product.

Through mentoring, the one-to-one contact offers the unique opportunity for the sharing of ideas, skills, and observations. If properly organized with two-way evaluations, both participants should benefit. Not all individuals, however, are suited for the role of mentor. Care should be exercised in the selection and pairing of mentors for the less experienced. Perhaps a human resource manager could assist in identifying those people with the interpersonal skills required for this teaching position.

Information from the product development area would be gathered from the formulator, analytical and microbiology testing groups, and the packaging development unit. Issues to be considered from these groups will be discussed below. A safety evaluation from the toxicology group and industrial hygienist should be completed before a scale-up effort. In today's regulatory climate, a concise and understandable summary must be provided regarding the risks associated with and procedures for proper handling of all chemical substances, whether drug actives or excipients. Failure to provide sufficient information to those not skilled in the art to make the decision to initiate a handling, weighing, or processing operation may lead to an unfortunate employee injury. Although an employee has a "right to know," employers have an obligation to provide the necessary warnings and training to minimize placing an employee at risk. The legal ramifications of improper training or notification are outside the scope of this article.

An opinion should be solicited from the patent department or a patent attorney. With the implementation of the General Agreement on Tariffs and Trade (GATT) accord, patents take on a new meaning. The impact of this legislation is far reaching, not only in the United States, where major revisions in the patent laws have been required and implemented, but also in many foreign countries where patents may be essentially worthless or not enforceable. In general, patents have an effective life of 20 years from the date of initial filing. Additional periods of exclusivity may be allowed, on application and when certain criteria are met, that extend the effective term of a patent. In summary, care must be exercised to ensure that proper legal protection of the novel concept has been secured in those areas where desired.

The drug regulatory affairs unit must also be involved with the product transfer to specify "how much" of "what" information is needed either to submit for a drug approval or to introduce a product to the marketplace. The goal here is to collect the proper amount and kind of data necessary to support the prerequisite filings, either internal or external to the company.

The corporate office commonly involves personnel from the production planning unit, engineering group, and new product coordination section, as well as from marketing, because each of these divisions has a vested interest in the success of the venture. It is important to identify the needs of those people at the corporate level to minimize delays caused by the "we did not know that we had to do this now" club. Activities such as product label preparation, copy for advertisements and promotional pieces, and package graphics may need to be initiated during the transfer program as not to lose valuable lead times. The acceptance or approval process in some companies is very labor-intensive and therefore time-consuming. This is one area where a detailed time and event plan has been shown to yield a significant impact on timely completion of a project.

Keeping the corporate participants informed becomes a pivotal task for the project manager in obtaining the final acceptance of the product by the corporation. Therefore, any time taken with those people involved at the corporate level to explain the steps involved in the transfer program is time well spent. Like any educational process, consistency and repetition enforce learning. It is incumbent on management to foster cooperation among individuals at the functional research and corporate centers, because the loss of time is the worst enemy an organization can face.

There are a number of individuals at the manufacturing site who must work as a team to ensure the timely and efficient completion of this transfer effort. The plant manager, technical director, production planning group, manufacturing area supervisor, and quality control and quality assurance units—as well as the plant engineering, packaging and transportation supervisors—must be informed as to their responsibilities. Personnel training must also be considered if the technology is new to the site. Last but not least are the contributions that the line mechanics and chemical operators can make to the program. They perform the necessary production functions daily. Their insight and practical experience are an invaluable resource that should not be overlooked.

The success of the transfer is dependent on the ability of the project leader to motivate employees to work toward a mutually beneficial goal, namely, introducing a new product that will improve consumer health and create jobs and increased profit for the company.

MOTIVATING PARTICIPANTS

Implementation of a positive return on involvement is one mechanism by which changes in responsibilities and tasks can be implemented. Changes here include the manufacture of new products or using new procedures to produce existing products. By involving personnel in the planning of changes, in discussing the resources necessary to complete the tasks, and in creating an environment in which innovation can thrive, the project manager should strive to realize the completion of the program quickly and efficiently with reliable quality at an affordable cost. At the same time, those who have worked to bring the program to completion should share a feeling of teamwork and a sense of accomplishment. Return on involvement encompasses the philosophy that employees are a key element in the successful introduction of any technology or product approval. Project managers must keep this in mind because they frequently depend on the cooperation of individuals outside their direct control to accomplish their goals.

PRETRANSFER CONSIDERATIONS

Several assumptions must be satisfied before the advancement of any product to plant scale-up trials. First, the marketing division should have examined the proposed product prototypes and agreed that the product meets their needs. Second, the intended commercial package configurations should have been selected. Although it is not uncommon to package portions of the first scale-up batch in a variety of formats, it is incumbent on the project leader to eliminate unnecessary packages to minimize the dilution of effort. Third, any constraints, such as cost or time, must be identified so that they may be given due consideration.

There is an important question to be asked, i.e., does the product meet the needs of the consumer? The development staff believes they have captured marketing's vision with their product offering; however, the marketing and sales units must concur. The decision is generally in the sales unit, because those people are responsible for making the product available to the consumer and, more important, they are responsible to see that the product meets the consumer demands, real or perceived. It is expected that any pertinent focus groups or market research studies would be completed before the scale-up effort. These studies help confirm the product concept and its viability in the marketplace.

The cost of a development program increases dramatically as the number of package configurations to

be advanced to commercialization increases. Selecting the proper package sizes, closures, colors, and neck finishes is compromised by the package composition and availability, and, finally, the intended use and cost of the unit. For example, a smaller unit lasting 1 month, such as a calendar pack, makes marketing sense for oral contraceptives for several reasons. Dispensing and unit sales are generally cyclic and more predictable, allowing for better profit projections. The calendar pack and monthly cost to the consumer not only position the product toward enhanced consumer acceptance but also toward better patient compliance, especially with expensive medications. In contrast, inhalation aerosol units, because of their pattern of chronic use, frequently contain sufficient doses to last several months. Suffice it to note, it behooves the marketing unit to work with financial analysts to determine the optimal product configuration and cost profile that maximizes consumer acceptance and convenience, unit turns, profits, and resources.

Constraints always exist but occasionally are not communicated accurately or promptly. Competition in the marketplace frequently causes introduction deadlines and endproduct cost constraints that must be considered during the initial phases of a development program. On the other hand, lead times for materials and personnel resources must be appreciated when commitments are made to timelines. Without planning in advance, the task may not be possible at all. Factors that influence decisions may originate externally as well as internally. Care must be exercised to address those issues that affect the timely completion of a project.

Physicochemical properties of raw materials and the finished dosage form should be characterized before any scale-up effort. Having methodology available and validated to compare batches is essential. For example, drug-release profiles and viscosities have the potential of being altered in scale-up by manufacturing procedures and equipment. Care must be exercised to maintain the desired profiles and other product specifications. The effect of batch size and process scale-up should be monitored closely.

Formulation and/or development of advanced drug-delivery systems such as microencapsulated molecules, transdermal patches, or liposomes are frequently accomplished in the laboratory. However, large-scale production of these dosage forms may be problematic because the same conditions of manufacture may not be attainable or desirable in the plant setting. Consultation with process development personnel during the finalization of the prototype development phase is one way of minimizing scale-up difficulties.

An area occasionally overlooked by the development staff is the necessity of securing confidentiality

agreements from vendors supplying technologies or services to a firm. All contractors should be required to execute a confidentiality agreement that specifically encompasses the technology and product being developed. These documents should be prepared, reviewed, and

executed by the appropriate legal and executive officers of both organizations. Especially when the science or product is not well-defined and patent protection has not been secured, such as with the development of novel, specialized drug delivery systems or new chemical

Fig. 1 Project technology transfer checklist. (Modified from Ref. 1.)

entities, this task must be completed expeditiously, and no work should be initiated until the agreements have been properly executed.

TRANSFER PROGRAM

Any development and technology transfer program should be reduced to a written document such as that shown in Fig. 1. An outline or checklist must be compiled to ensure that appropriate consideration has been given to relevant issues. This helps ensure also that all parties are approaching the task from the same perspective and priority. A manufacturing site must be designated and the appropriate personnel notified as to their involvement. The necessary information must be collected and disseminated to the involved parties. At a minimum, copies of the proposed formula, manufacturing and testing procedures, and safe handling considerations should be distributed to allow sufficient time for review and comment. A planning review session should be convened with representatives from the research, corporate, marketing, manufacturing, quality assurance, regulatory affairs, and engineering departments in attendance. Selection of the time and location of this meeting should be made to encourage maximum participation.

The meeting should be chaired by the project leader. It is his or her responsibility to determine the relevant issues to be discussed, to follow up that an agenda for the meeting is distributed, and to establish that minutes of the meeting are taken. Concerns that arise during this meeting should be noted and addressed because the purpose of the meeting is to draw from the experience of the participants to identify potential problem areas in the program. The tone of this session should be one of consensus and not one of autocratic rule. Motivation, communication, and cooperation must be stressed in the voice and actions of the project leader. This is the first step toward accomplishing the primary program objective, namely, the timely and informed transfer of a new product from the research arena to the production site. The following subjects should be discussed at the planning meeting:

- Validated analytical methods
 - Regulatory considerations
 - Rework procedures
 - Transportation
- Formula—handling and safety considerations
 - Raw materials
 - Manufacturing equipment
 - Manufacturing precautions
 - Manufacturing procedures
 - Packaging
 - Process validation
 - Specifications for raw materials, packaging components, and in-process and finished product

Each aspect should be reviewed to ensure that critical issues have been addressed. If an aspect is not relevant, it should be stated that it is not applicable to the program. An issue perceived as unimportant in one department may be a monumental task in another department. With new drugs and drug-delivery systems, this effort is critical to the success of a program.

FORMULA

Understanding the formula, its derivation, and its constraints is one of the first prerequisites to any development program. The feasibility of the formula may be established by reviewing the ingredients of the composition and explaining their function in the formula. It would be appropriate to review the claims and physical characteristics of the product while evaluating a sample so that the participants of a planning meeting appreciate the appearance and attributes of the product.

The safety evaluation completed by the toxicology group and/or industrial hygienist should be reviewed with the participants because they, as managers, will most likely assume the responsibility to protect the safety of employees who will work on this project. The employees' right to know must be protected further by keeping them informed of the potential risks to which they may be exposed.

Prerequisite safety information can be transmitted by draft material safety data sheets, especially for new drug actives and new drug products. Preparation of the draft document may lead to the question: Are the process handling procedures for this product necessary and appropriate? Those personnel involved in the manufacturing of drug products are cognizant of the concepts of inherent risk due to an agent's toxicity, and potential risk, due to exposure. Whether the new drug and/or product should be handled in an open environment, contained area, or in isolation must be determined by those people who are responsible for safety. In all cases, the procedures must be reviewed and approved by the individual responsible for the involved manufacturing and testing sites.

Comments about the prestability and finished product stability profiles should be presented as an overview of the new product's chemical stability. This will support the anticipated shelf life of the formula and its ability to withstand the "process shocks" normally encountered

during production scale-ups. The toxicity of the finished product should be discussed. This information ensures that a decision regarding the handling of the formula has been made based on generated data and experience. A draft or tentative material safety data sheet may be one route to disseminate this information.

Constraints on specific ingredients or sources of ingredients, cost of goods, or manufacturing equipment should be reviewed. Constraints must be considered when formula optimization is undertaken; however, optimizing formulas may be best addressed in the production environment because batch size and manufacturing equipment sometimes have been shown to render viable laboratory and small-scale formulas virtually inoperative in the plant. The experience gained during the manufacture of laboratory and scale-up batches is invaluable and should be shared with the participants, especially the production and quality assurance staffs, in written reports and follow-up meetings.

Many firms use a laboratory development report to record these activities. These data can be incorporated into a full project-development history. For new drug products, development histories are needed to fulfill regulatory directives. The detail necessary in any summary report depends greatly on the magnitude of the problems encountered during development and the corporate structure in which one lives. For some multinational companies, the product-development report serves as the basis of spreading interest in a new product across global borders.

RAW MATERIALS

Sources of raw materials, especially those critical to a new product's functionality, should be identified. Availability and costs should be ascertained to aid in the planning process. Care should be taken to ensure that new drug actives and, when possible, excipients are secured from vendors with a current acceptable FDA compliance profile and a drug master file.

Testing monographs including methods to ascertain a lot's chemical and, if necessary, microbiological integrity should be provided to the selected manufacturing site in advance so that the methods may be applied to the incoming supplies. Handling of materials including storage, disposal, and employee precautions should be documented, especially for new or potentially hazardous materials. Again, material safety data sheets (MSDS) for all materials used should be available and disseminated to the plant personnel before any exposure.

MANUFACTURING

Equipment

When new drugs and drug-delivery systems are developed in the laboratory, the correlation of the necessary production equipment may be very difficult indeed. For example, the shear needed to create the desired particle size of an emulsion with the help of laboratory equipment may pose serious problems in the selection of plant equipment necessary to reproduce the attributes of the product. Recording the speed of a laboratory mixer is not sufficient by itself for this task; definition of the operating principle and equipment design is necessary to accomplish the task.

Any equipment used in drug manufacturing, including packaging, should have undergone an equipment evaluation, including installation, operational, and performance qualification, following a written protocol. This is an important step in a process-validation program. Through this effort, the operating parameters and capabilities of a given piece of equipment are documented. Furthermore, should a major component of the equipment fail, installation of a replacement part of known specifications reduces and in many cases eliminates the need for revalidation of every product processed with that equipment. The equipment itself, however, must be shown to meet its previous operating capabilities before being placed back into service.

The availability, size, and surfaces or composition of the required equipment should be specifically identified so that the scale-up effort may be representative of a production run. A preliminary compatibility screen of contact surfaces should be completed before the selection of scale-up equipment. The location of the equipment in reference to other requirements, such as services or the packaging area, may be a factor in the selection of equipment. A cleaning-validation study should be conducted to ensure that no residues of active ingredient or cleaning agent remain after cleaning and that the equipment is suitable for production use again. Alternative equipment may be considered and used; however, experience will dictate its suitability.

Precautions

Any concerns regarding the handling of equipment or product by employees should be addressed in the planning stage. This is especially important with regard to environmental (particulate contamination or sterility) or atmospheric (oxygen, moisture, or light sensitivity) problems.

Procedures

Procedures should be clear and concise. Specific descriptions should be used when possible. For example, “pass the emulsion through a suitable colloid mill (Eppenbach mill) at a setting of 0.005 inch (0.12 mm)” is preferred to a description referencing a more general description of a piece of equipment. Process-validation testing is necessary using specific equipment, as described by design and operating principle.

Procedures should be realistic, and any instructions must be scale-oriented. Specific parameters may be necessary for manufacturing areas. For example, cooling or heating times are typically equipment-dependent. Cooling 1 kg in the laboratory in 15 min may take 4 hours for a 40,000-kg batch in the plant. Similarly, filtration of small batches in the laboratory may not provide the necessary information to predict filter life or flow rates needed for large-scale manufacturing.

Based on the experience gained during the pilot scale-up effort, a process flow chart should be constructed. It helps identify steps and issues in need of process-validation review. In addition, the timing of activities toward the scheduling of manpower needs, such as for in-process testing, is generally more apparent when viewed in the context of the total process.

Process-optimization parameters as identified during the pilot scale-up effort should be monitored during the production scale-up batch. In this manner, appropriate recommendations based on experience may be integrated into the production of future batches. Many optimization experiments may be efficiently incorporated into the process-validation program.

Packaging

The description, specifications, and test methods for any packaging configuration should be available to the plant before the production scale-up. Unit functionality and fit should be included as a practical use test in any specification. The plant equipment to be used in packaging should be evaluated for feasibility, speed, and contact surface compatibility. Preliminary evaluations of surface compatibility, discussed previously, should suffice as an early indication of packaging equipment suitability.

The availability of or lead time to secure the necessary packaging components that are representative of the commercially marketed package frequently places stress on the project timeline. Package costs and possible alternative packaging can be evaluated with bulk produced from this batch. Therefore, a course of action to minimize project failure resulting from an unsatisfactory package

may be appropriate. The resultant dilution of resources and increased project expense must be weighed in accepting this course of action.

The number of various package sizes to be filled from a batch may be critical. For example, for generic drugs, entire batches must be filled for the batch to be accepted by the FDA. Although the batch may be filled into numerous package formats, care must be exercised to fill a sufficient number of each format to ensure proper equipment set-up and that the filling speeds used are representative of a full-scale production effort.

Procedures for packaging the batch including fill tolerances and precautions such as aseptic handling or nitrogen gassing should be reviewed to state the requirements for acceptance in advance. As a part of this production scale-up effort, it may be desirable to evaluate the product's bulk stability in the storage tank or storage drums to establish limits on the length of time a batch may be held before final packaging. This is especially important if the bulk product is to be manufactured at one site and transported to another site for packaging. Storage container compatibility deserves appropriate attention also.

Finally, the personnel involved in packaging should be instructed on any safety and handling issues that might affect them or compromise the product's integrity. Whether it is for the development of new package formats, such as for intranasal drug administration or transdermal patches, or for more traditional delivery systems, such as cycle packs, solutions, or aerosols, the need to educate employees involved in the processing is essential to the transfer program's success. Identifying and controlling process variables are necessary while experience is gained, and the process is optimized and validated.

PROCESS VALIDATION

Each class of product has specific issues to be addressed for process validation. In general, variable process steps such as mixing times and temperatures should be validated. Many articles have been written regarding the validation of processes affecting pharmaceutical products (12–14). Protocols to evaluate those parameters that may affect a product's integrity should be agreed on by the R&D, regulatory, production, QA, and engineering staffs. During the preparation and packaging of the pilot production batch, generation of data toward improving the efficiency of these processes, as well as minimizing batch-to-batch variations, is very important because this information will serve as documentation to support the new product's commercial feasibility. Also, the

establishment of cleaning procedures and documentation of cleaning validation can be accomplished at this time.

There is no magic number of batches required to prove that a process is validated. Generally, the number of batches accepted is three. The technical complexities of and product sensitivities to variable parameters dictate how extensive a validation program is needed. Suffice it to note that the process must be controllable and reproducible and yield a product that meets the desired specifications.

QUALITY CONTROL AND QUALITY ASSURANCE

One of the purposes of the pilot production batch is to introduce the new product in its entirety to the functional areas of the site (manufacturing, packaging, and testing), that is, the release of raw materials and packaging components as well as in-process, bulk, and finished product testing should be completed at the site as if the pilot scale-up were a commercial batch.

In-process testing, bulk release before packaging, and finished product specifications are proposed. Specification limits are proposed based on the experience gained with smaller laboratory and scale-up batches. Any comments or concerns regarding the test methods and specifications should be addressed at this time. Reagents and equipment to complete the required testing must be available at the plant. A contact at the R&D analytical laboratory should be established to explain aberrant values or to answer questions.

Communication of requirements of time and manpower to the quality control department is a critical issue that must not be overlooked. Prompt attention to analysis needs does help keep the pilot production batch process moving forward. If microbiological release of bulk product is needed before packaging, the project timeline should reflect the time period (3–5 days) generally needed for this activity.

Sampling must be scheduled for release and stability testing using a statistically valid sampling program. This is especially important for stability studies. In this manner, the chosen samples are documented to be representative of the entire batch.

Batch documentation is an important factor. Preparation of master batch records in accordance with plant standard operating procedures (SOPs) should be followed by an approval of the document by the sponsoring division, usually the formulator or process development staff of the R&D unit. On completion of a batch, review of the batch records by the quality assurance group ensures compliance to GMP and that all necessary deviations from

and modifications to the manufacturing records are properly explained and documented.

THE MANUFACTURING TRIAL SCHEDULING DATE

At the conclusion of the planning meeting, any actions that must be undertaken before the scale-up should be documented and a responsible party identified. At the discussion of the trial date, time constraints must be considered, along with the availability of raw materials, packaging components, plant scheduling time, and personnel. Coordination of personnel and supplies is the responsibility of the project leader. The ability to lead and negotiate another individual's priorities helps bring the trials to completion on schedule.

Finally, arrangements for transporting raw materials and packaged finished products must be made to ensure that the scale-up effort is completed on schedule and that stability studies are initiated expeditiously. Participants should leave the meeting under the impression that one person is in charge of the project, that the program has been well thought out and documented, and that commitments will be honored. Early issuance of meeting minutes will reinforce the importance of individual responsibilities and serve as notice to the participants and their superiors that their cooperation has been solicited, is needed, and is expected.

COMPLETION

In review, the activities to be completed at the manufacturing site are:

- Release of raw materials and packaging components
- Manufacture and packaging of the trial batch
- Generation of data from in-process, bulk, and finished product samples
- Process validation, including equipment qualification and reviews of batch records, processing, cleaning validation, and on-site experiences
- Shipment of finished product to the research facility for testing

An exit interview with involved plant personnel offers an opportunity for their comments to be heard. Their efforts should be acknowledged and their input seriously considered and incorporated into the manufacturing document. Any differences that cannot be resolved at this time should be noted and studied further. The art of

listening and diplomacy must be used inasmuch as this forum must be one of cooperation and not one of confrontation.

At this meeting, a discussion about possible rework procedures may be appropriate. The ability to recover materials, especially expensive drug actives, is desirable. Early identification of steps where rework may be possible allows for procedures to be tested, verified, and put in place, should they be needed. For pharmaceuticals, rework procedures may be used only if they are appropriately documented, validated, and approved by the responsible corporate and government bodies. Rework procedures are not an automatic means for handling out-of-specification product lots but rather for identifying where an effort may be implemented successfully. Logistics and economics, as always, dictate whether a rework should be considered.

POSTPRODUCTION ACTIVITIES AND EVALUATION

Once the plant experience has been concluded, confirmatory analyses on duplicate samples for in-process, bulk release, and finished product previously tested at the plant site should be completed at R&D. In this manner, the proposed methods are challenged to yield similar results from different analysts in different locations. Discrepancies in values generated at this point must be investigated and resolved. Samples should be placed into the stability testing system according to the organization's procedures.

Finally, a report must be prepared and issued expeditiously summarizing the experience, reviewing each area's involvement, and proposing, if necessary, changes in the process or control methods. Timely and factual communication of project progress to the other corporate areas not directly involved in the scale-up, such as the marketing, finance, and purchasing units, draws their attention and commitment of resources. By fostering informed decision-making through directed written communication, the time required to plan or complete these activities to bring the product to market is minimized, and resource usage is optimized.

A formal postproduction trial review meeting should be held with representatives from the R&D, corporate, marketing, quality assurance, regulatory affairs, and production centers. Plans to commercialize the product or to submit documentation for government approval if this is the next step in the development scheme are outlined, contingent on the successful completion of a defined stability program. Agreement as to the suitability of all the factors involved in the preparation of the product

should be the result of this meeting, with a substantiating document in the form of meeting minutes or a signed "statement of concurrence" generated and distributed.

A monograph of all pertinent sections to support the product's introduction should be assembled, reviewed, and disseminated to the appropriate parties. This document should include:

- Manufacturing formula
- Draft label copy
- Raw material tests and specifications
- Manufacturing procedure
- In-process tests and specifications
- Finished product test methods and specifications
- Packaging component specifications and drawings
- Packaging component test methods
- Stability data on bulk product
- Stability data on packaged product
- Shelf-life projection of expiration dating
- Material safety data sheet for the product
- Bibliography

A projection of shelf life should be included to document the recommendation for the expiration date. Although accelerated stability data are frequently used to support expiration dating for up to 24 months, extension of dating beyond 24 months is based on real-time test results.

A bibliography of all project reports and memos should be assembled, including the development and validation reports. Ideally, the project leader should maintain a file in chronological order of all communications and reports. Compiling the file into a bibliography is a tedious task but one that, should the need to answer a question arise, will be well worth the effort. Product development histories and testing "quirks" regularly appear in these documents and in no other place. Skilled project leaders maintain an ongoing listing as a means of tracking a project. A bibliography for a new pharmaceutical product may be voluminous, and a reference to its location may be useful. The transfer of the project is considered complete when the first commercial batch is produced under the supervision of the manufacturing site without problems.

SUMMARY

This article has reviewed issues to be considered when organizing the transfer of pharmaceutical technology from the research arena to the production environment. Critical areas affecting the manufacture, packaging, safety, and quality of pharmaceutical products are discussed in relationship to their impact by the technology transfer

process. The necessity of a plan with input from the various organizational centers is emphasized. The success of the program is highly dependent on the communication and cooperation shared throughout the process.

THERMAL ANALYSIS OF DRUGS AND DRUG PRODUCTS

Daniëlle Giron

Novartis Pharma AG, Basel, Switzerland

INTRODUCTION

Thermal analysis techniques, in which a physical property is monitored as a function of temperature or time while the analyte is heated or cooled under controlled conditions, are fundamental techniques for the characterization of drugs and drug products, not only while processing or aging conditions may be simulated but while the methods gives access to thermodynamic data. Due to the different informations delivered, thermal analysis methods are concurrent or complementary to other analytical techniques, such as spectroscopy, chromatography, melting, loss on drying, assay, for identification, purity, and quantitation. They are basic methods in the field of polymer analysis and in physical and chemical characterization of pure substances as well as for mixtures. They find good applications for preformulation, processing, and control of the drug product. The introduction of automation considerably increases the advantages of these methods. New horizons are open with the availability of combined techniques and microthermal analysis.

PRINCIPLES AND EXPERIMENTAL FACTORS

Considering the number of physical parameters of a substance that may be measured, the number of techniques derived is very large. Details on most techniques are well described by Wendlandt (1). For pharmaceutical applications, the methods generally used are differential scanning calorimetry (DSC), thermogravimetry (TG) (or thermogravimetric analysis: TGA), and, to a lesser extent thermomechanical analysis (TMA). All techniques are automated and have data acquisition. Hyphenated techniques and modulated DSC are growing techniques, “state of the art” for the 21st century. Excellent books or review articles dealing with the principle, instrumentation, and applications of thermal analysis methods for pharmaceuticals are given in (1–15). As emphasized by Cheng et al. (14), tendency in the next two decades will be more precise and meaningful measurements in these techniques and new developments in obtaining

the temperature dependence of a material’s structure and dynamics.

Differential Scanning Calorimetry (DSC)

When a material is heated or cooled, there is a change in its structure or composition. These transformations are connected with a heat exchange. Differential scanning calorimetry (DSC) is used for measuring the heat flow into and out of the sample, as well as for determining the temperature of the thermal phenomenon during a controlled change of temperature. The first method developed by Le Chatelier in 1887 was differential thermal analysis (DTA), where only the temperature induced in the sample was measured.

The principle of DSC is as follows: two ovens are linearly heated; one oven contains the sample in a pan, the other contains an empty pan as a reference pan. If no change occurs in the sample during heating, the sample pan and the reference pan are at the same temperature. If a change such as melting occurs in the sample, energy is used by the sample and the temperature remains constant in the sample pan while the temperature of the reference pan continues to increase. Therefore a difference of temperature occurs between the sample pan and reference pan.

Manufacturers use two methods of measurements. In the first method called “heat flux DSC,” the instrument measures this temperature difference (DTA). Through calibration, this temperature difference is transformed into a heat flow, dq/dt . Therefore, there is a thermal factor that may vary with temperature. In the second method, called “power compensation DSC,” two individual heaters are used in order to monitor the individual heating rates of the two individual ovens. A system controls the temperature difference between sample and reference. If any temperature difference is detected, the individual heatings are corrected in such a way that the temperature is kept the same in both pans. That is, when an endothermic or exothermic process occurs, the instrument delivers the compensation energy in order to maintain equal temperature in both pans.

In the first case temperature is primarily measured, and in the second case, energy is primarily measured.

The differentiation of measuring principles is with modern instrumentation not very significant under normal applications. Due to calibration and integrated data handling, the instruments produce similar qualities of reported results.

Each instrument can deliver the same information, that is, heat flow as a function of temperature (or time). The peak shape, the resolution, and the sensitivity depend on the principle of measurement and the specification of the instrument.

For first-order transitions such as melting, crystallization, sublimation, boiling, etc., the integration of the curve gives the energy involved in the transition. For second-order transitions, the signal gives the change in the specific heat, for example, glass transitions.

Fig. 1 shows typical transitions. Melting and crystallization are first-order transitions. The extrapolated onset temperature (T_e) is the melting or boiling point. The peak temperature (T_m) is dependent on instrument and measurement parameters. The glass point is determined as inflexion point. Manufacturers represent the heat flow in different ways: the endotherms in the positive side for power compensation DSC and in the negative side for heat flux DSC. Melting, boiling, and sublimation are endothermic, which means they need energy. Crystallization is exothermic, which means that it supplies energy. Desolvations without melting are generally endothermic. Solid–solid phase transition and decomposition may be endothermic or exothermic.

Modern instruments provide heating, cooling and isotherms between subambient temperatures (with a cooling device) and higher temperatures in the range of 1200–1500°C. In order to avoid reactions with the atmosphere the measurements are carried out under nitrogen. The major components of the systems include the DSC sensors, the furnace, the programmer, and the data handling. The temperature plotted on the abscissa is the programmed temperature, not the temperature of the sample.

Fig. 1 Theoretical DSC scans.

The difference between the programed and the actual temperature of the sample is called “thermal lag.” It depends on the thermal resistance of the instrument and the heating rate. In modern instruments dedicated to accurate analytical measurements for pharmaceuticals, the sensors are in direct contact with the bottom of the pans and the sample size is in the milligram range or less. Therefore this correction is not very high, but it has to be taken into consideration. Generally pure indium (>99.9999%) is used for the correction of the thermal lag.

Great efforts have been made in recent years in order to validate the different instruments not only in comparing principle and results but also in determining the critical parameters such as heating and cooling rates, particle size, weight, resolution, atmosphere, and type of pans (crimped pan, sealed pan, open pan, etc.).

The instruments include automation and data acquisition. The calibration of the instrument should be done at a yearly basis. This includes the measurement of temperature and enthalpy. Most certified standards are highly purified metals. Indium is the preferred reference standard, but it covers only one temperature. It is recommended for pharmaceuticals to include several organic substances for which the melting point or the melting enthalpy has been accurately determined. Sarge et al. (16,17) proposed several organic substances and metals. The heat determination of quartz was also recommended. Sabbah (18) published recently a broad review of data of organic substances. For pharmaceuticals, it is suitable to have certified materials covering a broad range corresponding to the thermal events of interest (19).

Tables 1 and 2 are examples of calibration of the temperature and of the calorimetric response of PE-DSC-7 instruments by using different materials (20). Very important for pharmaceutical industry is the confidence of the laboratory that delivers the reference. Since the heating rate may have an influence on the data, it is recommended to compare the melting point and the melting enthalpy of organic standards, additionally to indium, at different heating rates covering the measurement range. For very accurate determinations, it is recommended to use standards with a melting point in the range of the considered temperature in a series of measurements.

Pressure DSC

In Pressure DSC (PDSC), the sample can be submitted to different pressures, which allows to characterize substances at the pressures of processes or to distinguish overlapping peaks observed, for example, by desolvation (21).

Table 1 Example of calibration of Perkin-Elmer DSC-7 instruments with melting standards at 10 K min⁻¹ under nitrogen

Certified substances	Onset T (°C) certificate	Instrument 1 Onset T (°C)	ΔT (°C)	Instrument 2 with intracooler Onset T (°C)	ΔT (°C)
Iodobenzene	-31.3			-32.2	0.9
H ₂ O	0.0			0.1	0.1
4-Nitrotoluene	51.5	50.4	1.1	51.2	0.3
Biphenyl	69.3	68.2	1.1	68.6	0.7
Naphthalene	80.2	79.4	0.8	80.1	0.1
Benzil	94.7	94.21	0.6	94.5	0.2
Acetanilide	114.0	113.9	0.1	113.6	0.4
Benzoic acid	122.1	122.0	0.1	121.8	0.4
Diphenylacetic acid	146.5	146.9	0.4	146.9	0.4

Anthraquinone	284.5	285.2	0.7	284.8	0.7
Lead	327.5	328.6	1.1	—	—
Zinc	418.9	420.3	1.4	—	—

Modulated DSC

This new technique introduced in 1993 (22) has been thoroughly examined and discussed (23). Main advantages are the separation of overlapping events in the DSC scans. In conventional DSC, a constant linear heating or cooling rate is applied. In modulated DSC (MDSC), the normally linear heating ramp is overlaid with a sinusoidal function (MDSC) defined by a frequency and an amplitude to produce a sinusoidal-shaped temperature versus time function. Using Fourier mathematics, the DSC signal is split into two components: one reflecting non-reversible events (kinetic) and the other reversible events.

$$T = T_0 + bt + B \sin(\omega t)$$

$$dq/dt = C(b + B\omega \cos(\omega t)) + f'(t, T) + K \sin(\omega t)$$

where T is temperature, C the specific heat, t the time, ω the frequency, $f'(t, T)$ is the average underlying kinetic function once the effect of the sine-wave modulation has been subtracted. K is the amplitude of the kinetic response to the sine-wave modulation and $(b + B\omega \cos(\omega t))$ is the measured quantity dT/dt or “reversing” curve.

The total DSC curve, the reversing curve giving reversible transitions and the nonreversing curve giving irreversible transitions (e.g. the glass transitions), is

Table 2 Examples of calorimetric measurements of standards with two different DSC-7 instruments and measurement cell at different times (A, B, C) at 10 K min⁻¹ under nitrogen

Standard substance	ΔH (J/g) (Theory)	A		B		C	
		ΔH (J/g)	% deviation	ΔH (J/g)	% deviation	ΔH (J/g)	% deviation
Naphthalene (80.2°C)	148.6	147.1	1.0	148.6	0.0	—	—
Benzil (94.7°C)	112.0	110.1	1.7	112.8	0.7	—	—
Benzoic acid (80.2°C)	147.2	—	—	—	—	146.6	0.4
Biphenyl (69.3°C)	120.4	120.0	0.6	—	—	120.5	0.1
Diphenyl-acetic acid (146.5°C)	146.9	—	—	146.8	0.1	—	—
Indium (156.6°C)	28.7	28.63	0.2	28.8	0.35	28.7	0.1
Tin (231.9°C)	60.2	60.0	0.3	—	—	60.8	1.0

obtained. MDSC is a valuable extension of conventional DSC. Its applicability (24) is recognized for precise determination of the temperature of glass transitions and for the study of the energy of relaxation, and it depends on a number of important parameters to be studied. It has been recently applied for the determination of glass transitions of hydroxypropylmethylcellulose films (25) and for the study of amorphous lactose (26), as well as for the study of some glassy drugs (27).

Microwave thermal analysis (MWTa)

In this new technique (28), microwaves are used both to heat a material and to detect thermal transitions.

Micro-DSC

The instruments of conventional DSC allows to measure very small amounts of material. The author was able to characterize the melting peak of indium with 0.032 mg by using a DSC-7 of Perkin-Elmer. New instrument generation will permit to increase sensitivity and amount of material to be studied decrease to nanorange (29).

Microcalorimetry

Microcalorimetry is a growing technique (30,31) complementary to DSC for the characterization of pharmaceuticals. Larger sample volume and high sensitivity means that phenomena of very low energy (unmesurable by DSC) may be studied. The output of the instrument is measured by the rate of heat change (dq/dt) as a function of time with a high sensitivity better than $0.1 \mu\text{W}$. Microcalorimetry can be applied to isolated systems in specific atmospheres; or for batch mode where reactants are mixed in the calorimeter. Solution calorimetry can be used in adiabatic or isoperibol modes in microcalorimeters at constant temperature. (See the corresponding article about calorimetry of this edition.)

Thermogravimetric Analysis

In thermogravimetry (TG or TGA) the change in sample mass is determined as a function of temperature and/or time. The instrument is a thermobalance that permits the continuous weighing of a sample as a function of time. The sample holder and a reference holder are bounded to each side of a microbalance. The sample holder is in a furnace, without direct contact with the sample, the temperature of which is controlled by a temperature programmer. The balance part is maintained at a constant temperature. The instrument is able to record the mass loss or gain of the

sample as a function of temperature and time [$m = f(T)$]. Most instruments also record the DTG curve, which is the rate of the mass change $dm/dt = f(T)$.

The DTG curves, allow a better distinction of overlapping steps, as demonstrated in Fig. 2, for $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$. The area under the DTG curve is proportional to the mass change, and the height of the DTG peak at any temperature gives the rate of mass change. The real advantage of DTG is to permit accurate location of the end of a desolvation process if decomposition follows desolvation by use of the minima in the DTG curve.

The instrument used in thermogravimetry is a thermobalance (balance controller, sample chamber, furnace, furnace controller) with data processing. In order to check the stability of the system a baseline at the highest sensitivity has to be done for all heating rates in the temperature range of analysis: The highest deviation will be observed at the highest heating rate. The thermobalance may have a vertical or horizontal construction. The sensitivity of new thermobalances attains $0.1 \mu\text{g}$. Some manufacturers offer combined DSC/TG instruments.

The mass accuracy is generally not a problem of modern TG. Calibration of the mass with certified mass can be used as for all other balances. Electrostatics, temperature fluctuation, sensitivity of the sensor, and thermal lags have to be known, what is best done with regular calibration. For automatic TG, the pans have to be tightly closed and pierced just before the measurement; therefore, the TG curves of desolvation may be different as for open pans. The use of a protective gas and its flow, as well as the sample mass and the heating rate play a role in the comparison of the temperature of thermal events. The influence of heating rate is exemplified in Fig. 3 with $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$. The limit of detection can be calculated by determining the maximum

Fig. 2 TG of copper(II) sulfate pentahydrate with the heating rate 20 K min^{-1} . Use of DTG for the different steps.

Fig. 3 TG of copper(II) sulfate pentahydrate. Influence of the heating rate. TG curves from the top: 20 K min⁻¹, 10 K min⁻¹, 5 K min⁻¹, 2.5 K min⁻¹.

of deviation of the base line in the temperature range of interest.

Table 3 shows an example of calibration performed with hydrates, which cover the starting of dehydration temperature from 50 to 120°C and the end of dehydration from approx. 150°C until to 270°C with different heating rates.

Since there is no contact between pan and furnace, the thermal lag is higher than in DSC. The standards recommended by ICTA and distributed by NBS are ferromagnetic standards exhibiting loss of ferromagnetism at their curie point temperature within a magnetic field: Nickel (354°C), Permanorm 3 (266°C), Numetal (386°C), Permanorm 5 (459°C), Trafoperm (754°C). The method does not permit the temperature measurement with high precision. These standards have been studied by several authors (32). The ICTA temperatures are within 5–10°C. McGhie et al. (33) proposed a calibration technique in which a small inert platinum weight is suspended by a fusible link composed of a calibration standard that releases the platinum weight at the temperature of melting. The Mettler instrument TGA 850 is constructed so that the melting curve of standards can be measured and used as calibration, as demonstrated in Table 4.

TG can be used with different atmospheres and under vacuum. TG has a huge number of pharmaceutical applications. Automated TG is extremely efficient to replace the loss on drying assay in drug substances, being able to separate loss of solvent from decomposition by using very small amounts of substance. Solvent entrapped or bounded as solvate is easily determined (9, 34, 35). A comprehensive article on TG has been recently written by Dunn and Sharp (36). Ozawa proposes the use of modulated TG for kinetic analysis (37).

Water sorption–desorption isotherms can be carried out by using thermobalances. Now specific instruments allow to measure water sorption–desorption isotherms at different constant temperatures (e.g., dynamic vapor sorption instrument (DVS), Surface Measurement Systems Ltd., Monarch Beach, US).

Thermomechanical Analysis

In thermomechanical analysis (TMA) the deformation of the sample under stress is monitored against time or temperature while the temperature increases or decreases proportionally to time. Changes are detected by mechanical, optical, or electrical transducers. The stress may be a compression, penetration, tension, flexure, or torsion. Generally the instruments are also able to measure the sample dimensions, a technique called thermodilatometry. The stress (F/A) expressed in N/m² or Pa may be a normal tensile stress σ , a tangential shearing stress τ , or a pressure change Δp ; the force applied is F and A is the area.

The deformation is measured by the strain, which is the deformation per unit dimension.

$$\text{Elongation} \quad \varepsilon = \Delta L/L_0$$

$$\text{Volume strain} \quad \theta = \Delta V/V_0$$

$$\text{Shear strain} \quad \gamma = \Delta x/y$$

For an elastic material, the Young's modulus is defined by

$$E = (F/A)/(\Delta L/L_0) \quad \text{or} \quad E = \sigma/\varepsilon$$

Creep is the gradual irreversible elongation of the sample.

Table 3 Example of calibration of loss of mass with three hydrate standards

Substance	Theoretical amount water	Result		
		5 K min ⁻¹	10 K min ⁻¹	20 K min ⁻¹
Sodium-tartrate dihydrate	15.7%	15.73%	15.60%	15.73%
Calcium-oxalate monohydrate	12.3%	12.55%	12.51%	12.48%
Copper-sulfate pentahydrate	36.1%	36.08%	36.03%	36.04%

Table 4 Example of calibration of the temperature of TGA 850 with melting standards

Substance	Theory	Result		
		5 K min ⁻¹	10 K min ⁻¹	20 K min ⁻¹
Nitrotoluene	51.5°C	51.49°C	51.64°C	53.78°C
Indium	156.6°C	157.62°C	157.38°C	157.74°C
Tin	231.9°C	233.44°C	233.42°C	233.68°C

These parameters depend on the temperature. The coefficient of thermal expansion is

$$\alpha = \left[\frac{dL}{dT} \right] \left[\frac{1}{L_0} \right]$$

The instruments have a furnace, and mostly a linear variable differential transformer (LVDT) to produce an electrical signal from a linear movement. An additional unit controls the force applied. Special attachments allow the same instrument to work in different modes such as elongation, compression, penetration, or tension.

The slope of the TMA trace may also be obtained by DTMA.

$$\frac{dL}{dt} = L_0 \alpha \frac{dT}{dt}$$

where dT/dt is the heating rate.

Thermomechanical methods are very useful for the determination of phase transformations such as polymorphic solid–solid transitions or glass transitions. Fig. 4 shows some theoretical curves for glass transition and polymorphic transition in extension or in penetration mode. Recently TMA has been proposed for the measurement of the internal stress of tablets of ethylcellulose of different molecular weight (38) and for measurement of swelling of polysaccharide hydrogels (39) and of polymeric films (40).

Calibration of the instrument for its response to length may be carried out with a standard length piece of metal or ceramic. The temperature can be calibrated in the same

way as for DSC. Metal standards such as indium, tin, or lead are mostly used. Recent publications (41) deal with calibration and errors of TMA.

Dynamic Mechanical Analysis

In this technique, the mechanical response of a sample is measured as it is deformed under oscillating load against temperature or time. Dynamic mechanical analysis (DMA) is a further development of TMA, but the instruments are different.

DMA is mostly applied to the study of polymers. Relevant parameters are the storage modulus and the loss modulus. Generally the loss $\tan \delta$, which is the ratio of these modulus, is plotted against temperature. A recent overview of the pharmaceutical applications of DMA has been published by Craig and Johnson (42).

Torsional braid analysis (TBA) is a particular case where the sample supported by a fiberglass braid is subjected to a torsional strain.

Hyphenated Techniques (Combined Techniques)

A comprehensive characterization of the physical properties of materials often requires a multidisciplinary approach since no single technique is capable of characterizing pharmaceuticals completely.

Thermomicroscopy or hot stage microscopy is a well-established method (43, 43–45) for the microscopic observation with polarization of the sample while heating

Table 5 Study of two polymorphs with unique melting curve

Property	Crystalline form A	Crystalline form B
Melting point °C	304	311
Melting enthalpy in kcal/mol	12	11

Transformation in alcohols	A	B → A

Fig. 4 Theoretical TMA curves for glass transition T_g and polymorphic transition.

or cooling, allowing to see desolvation, melting, crystallization, eutectic formation, and even transformations in suspensions in solvents. The combination of hot stage microscopy to new technology such as high-resolution color camera, image manipulation software makes the technique very attractive for inducing metastable states, for observation of crystal habit, and for better interpretation of other methods. Thermophotometry is the measurement of the light intensity and thermoluminescence of the light emitted by the sample. FT-IR microscopy (15, 45, 46), Raman microscopy (47–49) are excellent additional tools to thermomicroscopy. Calibration of microscope, of heating unit, and of spectroscopic methods should be done. TEM (transmission microscopy) and SEM (scanning electron microscopy) with EDX have been combined to DSC for the study of solid-state reactions.

Newly born, the scanning thermal microscopy derived from atomic force microscopy brings a revolution in the instrumentation for measuring thermophysical and thermomechanical properties of the matter, and the TA instrument was awarded at Pittsburgh 1998. The instrument has been applied for the characterization of Ibuprofen compacts as model substance (50).

Temperature-resolved X-ray diffraction with a heating cell is widely used (12, 51–54). Crystalline changes are clearly assigned; the X-ray diffraction patterns obtained *in situ* allow to predict quantitative methods if, for kinetic reasons, forms that are present at high temperatures occur at ambient conditions. Low-temperature X-ray diffraction cell has been developed for the study of frozen aqueous solutions (55). The introduction of XRD-DTA cell (56) and recently of the DSC-XRD instrument of Rigaku presented at the Denver X-ray Conference in 1999 (57) demonstrates the advantage of this direct combined technique. The observation of polymorphic transformation by using variable temperature synchrotron X-ray diffraction method is a promising technique with the new computerized ability for obtaining structural data (58).

Thermogravimetry can be coupled with DSC. Most companies offer the TG-IR (59) or the TG-MS coupling

(60). Synergic chemical analysis by coupling TG-FT-IR, TG-MS or TG-GC-MS has been recently discussed (61). Fig. 5 demonstrates the ability of TG-MS for the study of dehydration and decomposition of calcium oxalate dihydrate. The steps correspond to the dehydration into anhydrous calcium oxalate, followed by the transformation into calcium carbonate then by the formation of calcium oxide (10, 11). The sample studied in Fig. 5 contains additionally to crystal water some free water. The TG-MS shows that some amount of the CO evolved during the decomposition also transforms into CO₂.

These new emerging combined techniques enables the observation of extremely small samples with a high degree of information. They find a good place for proper screening (55) (according to the polymorphic studies required by ICH) (62) in order to choose the proper form and to justify its choice. They also permit to analyze more easily the complex matrixes of drug products.

APPLICATIONS OF THERMAL ANALYSIS TECHNIQUES FOR DRUG SUBSTANCES

The transitions observed by thermal analysis techniques are based upon the Gibbs phase rule and phase diagrams, p , T , concentration.

All transitions or reactions involving energy changes may be measured by DSC. Transitions involving mass changes are detected by TG. For a single product, specific heat, glass transition, melting, boiling, sublimation, decomposition, and phase transitions induced by polymorphism during heating are important for the choice of the salt form and for safety studies where the DSC exothermic peaks are relevant. The use of DSC for the measurement of the melting point of raw materials has been proposed (20). Hydrates or solvates, or volatile compounds in the formulations can be investigated by DSC combined with TG and TG-MS. DSC curves of mixtures of solid compounds depend upon the phase diagrams in solid state. If there is no interaction in the solid state and if there is a miscibility in the melt, an eutectic behavior is observed. This enables the purity determination of raw materials, the analysis of enantiomers, and the study of “physical interactions” in preformulation. If the compounds are not miscible in the liquid state, the DSC curve of the mixture is the addition of the DSC curves of each compounds. Interaction is observed in the solid state in case of formation of solid solution or complex formation between components or in the case of chemical reaction.

Fig. 5 TG and TG-MS of calcium oxalate monohydrate. The TG steps correspond to the dehydration followed by the formation of calcium carbonate, then calcium oxide is obtained. The evolved gas is detected by MS.

Polymorphism/Pseudopolymorphism and Amorphous State

Polymorphism is the tendency of any substance to crystallize into different crystalline states. The solid forms of the same compound are called polymorphs or crystalline modifications. On melting, they produce the same liquid. Polymorphs show the same properties in the liquid or gaseous state but they behave as different substances in the solid state. The best known example of polymorphism is carbon, which can exist in the form of graphite or as a diamond.

The amorphous state characterizes crystallization in a nonordered, random system, related to the liquid state. The name “glassy state” is given to amorphous products that liquify by undergoing a glass transition.

The expression pseudopolymorphism applies to hydrates and solvates.

Different solid phases that may occur during crystallization or galenical processes are polymorphs, amorphous phases, or solvates as the result of compound formation with the solvent (63–66).

A recent detailed review about thermal analysis of polymorphs and pseudopolymorphs (67) listed more than 300 drug substances presenting this behavior in the literature. Polymorphism of excipients and their thermal analysis has been reviewed in (68).

DSC gives not only temperature of events, but also melting energies. The Burger's rule and the energy diagrams (69–74) help considerably to approach the thermodynamic equilibrium of a polymorphic system.

For each polymorph (single compound), there is a solid–liquid equilibrium curve and a solid–gas equilibrium curve. The solid–gas curves meet at a point. If the liquid–gas equilibrium curve meets the two solid–gas curves *after* this point of intersection, there will be a solid 1, solid 2 equilibrium curve and a reversible transition point $1 \leftrightarrow 2$ at a specific pressure. This is known as *enantiotropy*. At the transition point, the free energy of the two forms is the same.

The term *monotropy* applies in the case of an irreversible transition from one form to another. Monotropy is bound to the existence of metastable thermodynamic forms. The liquid–gas curve crosses the solid–gas curves for the two forms *before* their point of intersection.

Knowing the relationship between the thermodynamic quantities H (enthalpy), G (free energy), S (entropy), and T (temperature), it is often simple to represent equilibrium states by plotting the free energy G as a function of the temperature for each form. If the two curves intersect before the melting point, there is reversibility, i.e.

enantiotropy, and if the reverse is true, there is *monotropy*.

The relationship between melting enthalpies of two solid phases A and B and the heat of transition is:

$$\Delta H_t = \Delta H_A^f - \Delta H_B^f$$

Figs. 6A and 6B illustrate the plots of the functions G and H versus temperature (energy/temperature diagrams) for each polymorph and for the liquid. The thermodynamic reversibility of the solid transition between two crystalline forms is characteristic of enantiotropic systems. Each form has its thermodynamic stability range. The lower melting form is stable in the temperature range below the transition point; the higher melting form is stable in the temperature range above the transition point. In case of monotropy only one form is stable whatever the temperature range. The Burger's rule is as follows in the case of *enantiotropy*, the lower melting form has the higher melting enthalpy and the transition into the high melting form by heating is endothermic; in the case of *monotropy*, the thermodynamic stable form is the higher melting form with the higher melting enthalpy. The transformation of the unstable form into the stable form is exothermic.

Because of kinetic factors, metastable forms are encountered in temperature ranges outside the thermodynamic range. Crystallization processes generally imply the cooling of concentrated solutions or precipitation by addition of cosolvent. Depending on the relative positions of

Fig. 6 Energy diagrams showing plots of enthalpy H and Gibbs free energy G , against temperature T , for the solid and liquid phases of a single compound, showing (A) enantiotropy and (B) monotropy.

the solubility curves of the metastable polymorphic forms and the metastable curve of supersaturation, the first nucleus can be a metastable form. Transformation to the stable crystalline form may or may not occur, depending on kinetic factor. Furthermore solvates exist at lower temperatures and their presence should be considered and finally due to the humidity of the air or from water activity of the solvents, hydrates may be formed. Polymorphism of solvates and hydrates is not uncommon. This phenomenon of concomitant polymorphs has been recently reviewed (75).

Fig. 7 illustrates the behavior of polymorphs A and B in case of enantiotropy (Fig. 7a) and monotropy (Fig. 7b) during heating. For all analysis where a temperature change is involved, kinetic factors have to be considered for proper interpretation of the results. The DSC scans will differ if the sample being analyzed is stable or metastable at ambient temperature. A is the stable form at ambient temperature in both cases.

In the case of *enantiotropy* (Fig. 7a), only the form A should be encountered below the transition point and the behavior upon heating is illustrated by the DSC scan 1, the endothermic transition $A \rightleftharpoons B$ should be observed followed by the melting peak of the form B. For kinetic reasons, e.g., in case of too quick heating rate, the transition $A \rightleftharpoons B$ does not occur and form A melts. Then two possibilities may be found: no other signal occurs (DSC scan 2) or an exothermic crystallization of B from the melt occurs and later on, the melting peak of B is observed (DSC scan 3). If the metastable form B occurs below the transition, upon heating it can be transformed into A with an exothermic transition (DSC scan 4);

thereafter, the form A transforms into the form B according to scan 1 or scan 2). Finally (scan 5), the metastable form B can melt without any transformation.

In the case of monotropy (Fig. 7b) only the form A should exist and the DSC scan should show the melting peak of the stable form A (scan 1). If the metastable form B is heated, then scan 2 or 3 may be observed: the form B transforms exothermically into the stable form A (scan 2) or the form B melts and the stable form A grows from the melt and its melting peak is observed.

In the case of racemate, the situation is more complex since one racemate polymorph can be a true racemate and the other one a conglomerate (73, 74) and one has to consider additional solid phase transitions such as peritectoids and eutectoids, which are not polymorphic transitions (76).

Very often some substances have two melting points separated by an exotherm. Such a DSC scan can correspond to a monotropy or to an enantiotropy. The sample may be a pure form or a mixture. Using different heating rates and tempering in DSC, one may be able to measure melting points and melting enthalpies and to use the Burger' rule.

The TG curve is extremely valuable for preventing misinterpretations. McCauley (77) describes the DSC curve of phthalylsulfathiazole, which presents such a DSC curve with two endothermic peaks separated by an exothermic peak. The TG curve demonstrates a strong decomposition during the first melting. The resulting degradation product then recrystallizes and melts at higher temperatures. We observed such an effect for aspartam

Fig. 7 Possible DSC curves for two polymorphs: (a) Enantiotropy $A \rightleftharpoons B$, B is the highest melting form, A is the stable form below the transition point. (b) Monotropy $B \rightarrow A$, A is the highest melting form. (For explanations of the scans, see text.)

Fig. 8 Reversible transition in a purine derivative studied by DSC and temperature-resolved X-ray powder diffraction (From Ref. 67.)

(13) and for a malonate salt, which decomposed in the corresponding base (12). If an isomerization takes place, then only the analytical data of the product obtained allow us to have an accurate interpretation.

These curves illustrate the complex transitions that may occur when heating or cooling polymorphs. Therefore, combined techniques are very useful for complete interpretation of observations given by DSC as emphasized in (54). Fig. 8 illustrates a reversible enantiotropic transition followed by DSC and by temperature-resolved X-ray diffraction of a purine derivative. For this substance

six crystalline forms were found. The Burger's rule as well as the study of the supersaturated solutions and the use of combined techniques allowed us to find out that the form of Fig. 8 was the stable form below the transition point. All other forms were monotrops to this form (78).

Table 5 deals with the example of a benzoquinoline hydrochloride for which both forms presented a melting that was followed by decomposition. No change was observed by slow heating rate. Since the melting enthalpies differed only by 10%, the proper interpretation needed the verification of the hypothesis:

enantiotropic transition. The analysis of the insoluble solid in the equilibration of both forms in alcohols (solvent mediated transition) showed that form A is always obtained, what confirmed the observation of the Burger's rule.

Amorphous State

If a physical property of a crystalline substance is plotted against temperature, a sharp discontinuity occurs at the melting point. For amorphous substances, there is no melting point, and a change of slope occurs at the so-called glass transition temperature T_g . The glass transition is characterized by a change of heat capacity. Below this temperature, the amorphous phase has certain properties of a crystalline solid (e.g., plastic deformation) and is termed "glassy." Above this temperature, the substance retains some of the properties of a liquid, e.g., molecular mobility, and is termed "rubbery." Above this temperature, the increase in molecular mobility facilitates spontaneous crystallization into the crystalline form with an exothermic enthalpy change after the glass transition. The use of amorphous forms is attractive, particularly for sparingly soluble compounds because of the enhanced solubility and dissolution rate over the crystalline state leading to increased bioavailability. However, the amorphous state is thermodynamically unstable. The glass transition temperature T_g is lowered by water or other additives, facilitating conversion to the rubbery state and hence facilitating crystallization (79). Since it may be interesting to maintain the amorphous state, the temperature of the glass transition and its behavior should be characterized. DSC and modulated DSC are commonly used. Hancock and Zografi studied intensively the amorphous state of drug substances and used the relaxation energy at the glass transition as well as the dependency of the heating rate for the study of the "fragility" of the amorphous state (80–82). Depending on the temperature, the isothermal crystallization in one or the other polymorphic form may be favored as demonstrated for amorphous indomethacin (83).

The study of the amorphous state (for drug substances and also for excipients) is based upon the changes observed in the glass transition. Fig. 9 shows the influence of the heating rate for the determination of the glass transition by DSC for the polymeric excipient Carbopol 974. It is classical to perform a first run for the elimination of water and relaxation energy and to determine the glass transition temperature T_g of the pure compound, if no degradation occurs during the first run. However, this procedure is not valid if it is desirable to study the role of the matrix.

When the amorphous material does not transform into the crystalline material, the measurement of the melting

Fig. 9 Quality control of excipients by using the glass transition. Example of Carbopol 974 P. Second DSC run in order to eliminate water and relaxation: Influence of the heating rate.

peak allows to determine the degree of crystallinity of mixtures by comparing its value with the melting enthalpy of a pure crystalline material. If the amorphous sample crystallizes upon heating, then the crystallization peak may be used for the determination of the amorphous content. Such an example is given in Fig. 10. In this case it was possible to attain a limit of detection of 1%.

Pseudo-polymorphism

In the case of solvates, binary phase diagrams of temperature versus concentration of the solvent (or water) at a given pressure are useful for the understanding of the phase transitions. The characterization of solvates and hydrates need the use of both DSC and TG. Desolvation can be complex: melting of the solvate followed by exothermic recrystallization into the anhydrous form or solid-state transformation with evaporation and possibly further endothermic or exothermic events corresponding to a cascade of phase transitions. In such complex situations, combined techniques TG-IR or TG-MS and temperature-resolved X-ray diffraction are extremely helpful since the identity of the volatile component or of possible volatile decomposition product can be identified on line (54, 67). In case of hydrates, water sorption–desorption isotherms as well as the X-ray diffraction in humid chambers are needed (54, 84).

The DSC, TG curves of solvates and hydrates are related to the phase diagrams between substance and solvent (or

Fig. 10 Determination of amorphous content by DSC at 20 K min⁻¹. 1) Crystalline sample, 2) amorphous sample, 3) exotherm of a sample containing 4% amorphous as calculated by DSC. Calculation of the limit of detection by peak/noise ratio.

water). Eutectic are observed (85). Fusion or decomposition of the solvate may occur during heating. Therefore, one may observe the melting of the solvate followed by recrystallization into the anhydrous form or the endothermic desolvation in the solid state. In certain cases both phenomena may overlap. Details about experimental factors and examples can be found in (67). If the anhydrous form is metastable, further phase transitions follow the desolvation. If several solvates or hydrates exist, the transitions observed depend on the pressure, as demonstrated by Soustelle (86) in the case of copper sulfate pentahydrate. Depending on the pressure, the direct dehydration into the anhydrous or the dehydration via the monohydrate, or the three dehydration steps trihydrate, monohydrate and anhydrous forms may be obtained. Hydrates have been the subject of several reviews (87, 88). Polymorphism of hydrates (89) is also frequent. Figure 11 shows the case for a drug substance with polymorphic behavior of the trihydrate. The anhydrous form shows a dual melting (enantiotropy). This form was very hygroscopic and transformed into the trihydrate H_I at room temperature. The DSC scan of this trihydrate shows a dehydration peak in solid state, followed by the same scan as on the original anhydrous form. After storage for several months in a tropical climate (30°C/75% RH), a second trihydrate H_{II} is obtained. The same trihydrate H_{II} is also

Fig. 11 Polymorphism of a trihydrate. (From Ref. 10.)

obtained by crystallization in water or after equilibration of the original anhydrous form with saturated aqueous solution. The DSC scan of this trihydrate differs from the first one because the dehydration gives rise to a new anhydrous form. This interpretation was confirmed by X-ray Guinier de Wolff diagrams, purity analysis, Karl Fischer, and TG (10, 67).

Often the solvates (hydrates) are not detected since, according the corresponding phase diagram, at ambient temperature, they can be partly or completely dissociated. Suspensions of hydrates in water should shift the equilibrium toward the formation of the stable hydrated form. The ability of DSC measurements at subambient temperatures allow to determine phase transitions. Giron et al. (90) proposed to use the melting peak of freezable water for the analysis of suspensions of drug substances in water in combination with TG for the determination of the number of molecules of water bounded as hydrates.

Study of Transition: Kinetics

Since transitions may occur during milling, processing, and aging, thermal methods are widely used for the kinetic study of all transformations. The purpose of any kinetic study is to obtain information concerning the reaction mechanism through comparison of a series of measured

fractions converted versus time. Most mechanisms in solid state are a nucleation period, a growth zone, and an unreacted core. For phase transitions of polymorphs and pseudopolymorphs, only heterogeneous kinetic applies (at least two modifications or two phases and a gas). In heterogeneous kinetic a great number of factors should be considered as temperature gradient in the sample, particle size, activation, nucleus, or diffusion.

A summary of current kinetic methods used with thermal analysis techniques can be found in (67).

Microcalorimetric Techniques

Solution calorimetry allows us to investigate processes that involve enthalpy changes. Adiabatic microcalorimeters and isoperibol calorimeters used in batch modes or flow modes allow for the precise determination of the heat of solution. Mixing the reactants is accomplished by breaking a bulk allowing reactants to mix or by special chambers where the reactants are mixed together.

If a compound exists in two or more different crystalline or amorphous configurations with different lattice energies, the heating solution in any given solvent will differ. The difference in the heats of solution will be equal to the difference in lattice energy of the solids, provided that the solid compounds are identical chemically. For example, we measured the energy of solution in water of the two modifications of a drug substance. The difference of 9.7 kJ mol^{-1} was found very close to the difference of the melting energies of 9.1 kJ mol^{-1} measured by DSC (54). However, the DSC information is superior since the temperatures of melting of both forms are measurable. Since the lower melting form had a lower melting energy, it was the stable form and both forms were enantiotropically related. For review see Ref. 67.

Byström (91) developed a technique in order to determine the crystallinity of drug substances by isothermal microcalorimetry. Considering that micronization introduces amorphous regions not measurable by X-ray diffraction, the method should be an analytical tool

for analyzing batch-to-batch quality. The principle of the measurement lies in the transformation of the amorphous state in the crystalline one at high humidity levels. The amorphous substance adsorbs water and the glass transition is lowered, permitting the acceleration of the crystallization. The energy evolved is measured in function of time by isothermal microcalorimetry. Results were found comparable with X-ray diffraction but a quite lower limit of detection is possible (better than 1%) (54, 92, 93).

DSC Purity Analysis

The basis of any calorimetric purity method is the relationship between the melting depression of a substance and the level of impurities according to van't Hoff's law. The purity is readily calculated from the DSC curve of a single melting event of a few milligrams of the substance, without the need for reference standard of the drug substance and its impurities.

The DSC impurity analysis is described in USP. With modern equipment including robotic systems and data acquisition, the DSC purity analysis is a state-of-the-art technique for pharmaceutical development.

The determination of purity by means of DSC is based on the assumption that impurities depress the melting point of a pure material according to the eutectic phase diagram behavior.

Figure 12 shows the phase diagram for the two component mixture with the so-called eutectic point. At the eutectic point E (e.g., 40% A, 60% B), the crystals A and B melt together at the temperature T_E , below the melting temperature of the pure compounds. If a mixture of A and B (containing, e.g., 90% A) is heated, the melting of eutectic mixture (which is 40% in A) is observed initially, until all of B is melted. During the melting of the eutectic (40% A, 60% B) a part of A is melted with B, with the corresponding amount $2/3 \times 10\%$ of A, i.e., 6.66% of A.

Then as the temperature increases, pure A melts between T_E and T_m . T_m is the temperature at the end of the melting. For the corresponding DSC curve, an endotherm

Fig. 12 Binary phase diagram with eutectic, and DSC curve of the composition x_2 .

Fig. 13 Broadening effect of the melting curve of β -hydroxypropyltheophylline due to impurities. PSA = phase solubility analysis. All batches have the same TLC purity results. (From Ref. 6.)

at the eutectic temperature is observed, then the melting of crystals A occurs. The effect of impurity on the DSC curve is a melting depression and a broadening of the melting curve (Fig. 13).

The amount of impurities is calculated from the melting-point depression $\Delta T = T_0 - T_m$.

The van't Hoff's law for *diluted solutions* is

$$x = \frac{(-\Delta T \Delta H_f)}{RT_0^2}$$

where x is the mole fraction of impurities, ΔT the melting point depression, ΔH_f the melting point of pure material, T_m the melting of the analyte, T_0 the melting point of the pure compound, and R the gas constant.

The DSC procedure does not directly measure ΔT , but can be used to calculate it from the melting curve. At the eutectic point, all of B is in the liquid phase. During the melting of A after the eutectic point the concentration of B varies in the liquid phase. This causes the broadening of the DSC curve. With no solid solution formation, the concentration of impurity in the liquid phase at any temperature during the melting is inversely proportional to the fraction melted at that temperature, and the melting-point depression is directly proportional to the mole fraction of impurity. A plot of the observed analyte temperature T_i versus the reciprocal of the fraction melted $1/F_i$ at temperature T_i should yield a straight line with the

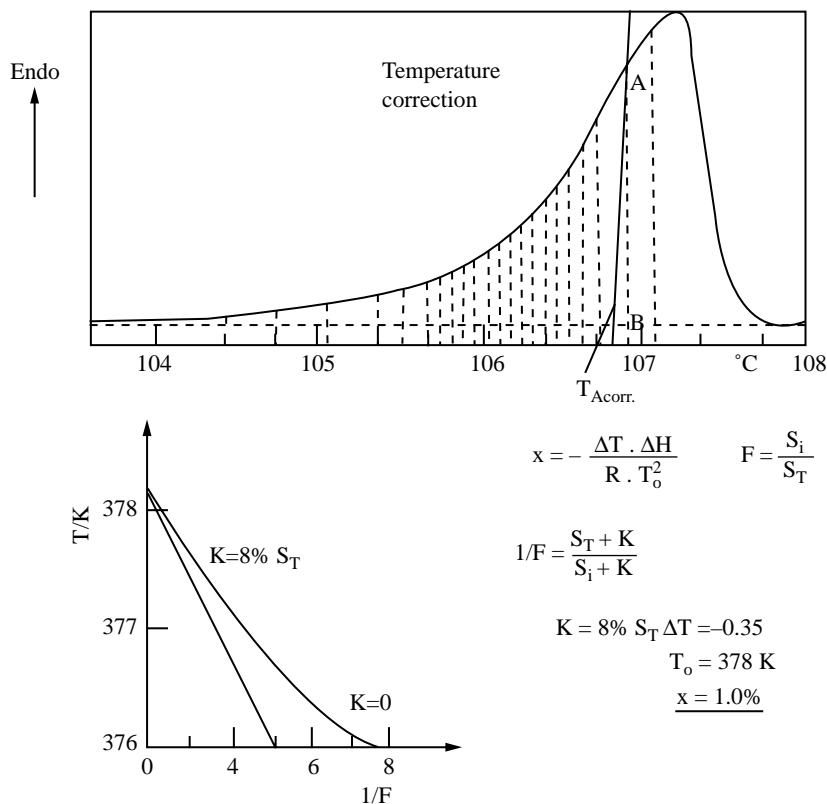

Fig. 14 Purity calculations by DSC.

slope equal to the melting-point depression ($T_0 - T_m$). The theoretical melting point of the pure compound T_0 is obtained by extrapolation to $1/F_i = 0$:

$$T_i = T_0 - \frac{RT_0^2(1/F_i)}{\Delta H_f}x$$

This relation may be expressed as

$$T_i = T_0 - \Delta T(1/F_i)$$

Substituting the experimentally obtained values for ΔT , ΔH_f , and T_0 in the first equation yields the mole fraction of the total eutectic impurities, which, when multiplied by 100, gives the mole percentage of total eutectic impurities.

The temperature of each point T_i is the sample temperature, not the programmed temperature. Due to the thermal lag, a correction depending on the instrument has to be done for each point.

The melting curve is divided into small portions and each area S_i is calculated. The melted fraction F_i ,

$$F_i = \frac{S_i}{S_{\text{total}}}$$

is calculated for each point and the curve T_i is plotted as a function of $1/F_i$, where T_i is the temperature at fraction F_i (Fig. 14). The slope ΔT and the ordinate T_0 can be calculated.

Partly because of the lack of the eutectic-point detection, the curve is not a straight line, and a correction factor K must be added to each fraction of the curve. Formation of solid solution or artefacts during melting may also be responsible.

$$F_i = \frac{S_i + K}{S_{\text{total}} + K}$$

Software from manufacturers mostly use iterative linearization, which gives the best value of K . Characteristics of this determination are as follows:

- Impurities are measured, which have an eutectic behavior (i.e., solubles in the liquid phase and insolubles in the solid phase).
- The sum of impurities should be $\leq 2\%$.
- The result is expressed in mol % without knowledge of impurities.
- Pure material is not needed.
- Small amounts (1–2 mg or less) of material are used.
- If decomposition occurs during melting, it can give erroneous results.
- The purity results are obtained after less than 1 h.

The influence of products parameters and instrument parameters have been discussed in detail by Giron et al.

Fig. 15 Stability screening. Example of DSC purity results obtained for a drug substance sensitive to moisture. From the top to the bottom: Initial sample (purity 99.9%), sample stored under humid conditions at 50°C (purity 99.7%), sample stored under humid conditions at 80°C (purity 99.1%).

(94), who proposed a validation scheme for DSC purity method. The authors showed the advantage of the method as support to chromatographic techniques, for the monitoring of purification for the study of stability behavior of raw materials under stress conditions, for establishing purity profiles. Fig. 15 shows the DSC scans corresponding to a stability screening of a drug substance sensitive to moisture.

Enantiomers

Enantiomers are stereoisomers, which are mirror images of each other. An equimolecular mixture of two enantiomers is called a racemate. Crystalline racemates occur in three different types. The first is termed a conglomerate, that is, a mechanical mixture of crystals of pure enantiomers that is formed from two solid phases. The most common type is the racemic compound, which consists only of one crystalline phase in which the two enantiomers are present in equal quantities. The third type is the pseudoracemate in which a solid solution of the two enantiomers is present.

Conglomerates that are equimolecular mixtures of two crystalline enantiomers are easily separated by crystallization. There are two phases in the solid state and only one phase in the liquid state (miscibility). The equation of Schröder–Van Laar in its simplified form correlates the composition of mixtures to the end of fusion T^f :

$$\ln x = \frac{\Delta H_A^f}{R} \left[\frac{1}{T_A^f} - \frac{1}{T^f} \right]$$

where x is the mole fraction of the more abundant enantiomer ($0.5 \leq x \leq 1$) of a mixture that melts at T^f (in

K). ΔH_A^f and T_A^f are respectively the enthalpy of fusion and the melting point of the pure enantiomers, and R is the gas constant.

Racemic compounds, or true racemates, exhibit two eutectic points each between the pure enantiomer and the racemic compound. The shape of the DSC diagrams can vary, depending on the relative positions of temperatures of eutectics and racemic compound and on the composition of the eutectics (Figs. 16b and 16c). In the case of Fig. 16c it is difficult to distinguish by DSC a racemic compound from a conglomerate. Other methods as IR or X-ray are suitable for proper interpretation. For example, propanol hydrochloride has been described as conglomerate (95) or as racemate compound (96).

The equation of Schröder–Van Laar, which permits the calculation of the liquidus curve, may be applied to the point of the liquidus between the pure enantiomers and the corresponding eutectics (T_{AE}^f and T_{AS}^f). For the part E_RRE_S , the equation of Prigogine and Defay applies:

$$\ln 4x(1-x) = \frac{2\Delta H_R^f}{R} \left[\frac{1}{T_R^f} - \frac{1}{T^f} \right]$$

where x represents the mole fraction of the enantiomer in the mixture that melts at T^f and ΔH_R^f and T_R^f are respectively the enthalpy of fusion and the melting point of the racemic compound. Polymorphism can occur for the racemic compound and the enantiomers. Phase diagrams with monotropic transformation or enantiotropic transformation have been discussed (75, 76). Quite interesting is the transformation of the racemic compound into a conglomerate since this phenomenon can be used for purification via crystallization, as described for nimodipine (97). DSC is applied for the establishment of phase diagrams, for the determination of thermodynamic data (98), for the purity determination, or for the monitoring of industrial resolutions. For the establishment of phase diagrams it is suitable to add spectroscopic or crystallographic methods (99).

Two methods can be used for the purity determination: the direct method or the indirect method (75). The direct

method is applied for mixtures when the phase diagram is established using Schröder–Van Laar or Prigogine–Defay equation. For enantiomers of high purity (>95%) the general DSC purity method for eutectic impurities is applicable. The same limitations remain (polymorphism, degradation, during melting). The method gives the sum of impurities without differentiation of the type of impurity. For purity > 95% the same results have been obtained using the indirect and the direct methods (100, 101).

Conglomerates are easy to purify by crystallization or by the entrainment technique described by Jacques et al. (75), which involves introducing seed crystals of the desired enantiomer into a cooling saturated solution of the racemic mixture. According to these authors, conglomerate formation is observed three times, more frequently with salts. Therefore it is advantageous to compare the behavior of salts forms. On the other hand, for a synthesis in several steps, it is useful to study the behavior of each step in order to choose the step exhibiting a conglomerate behavior resulting in an efficient enantiomeric resolution. In the case of racemic compound, the entrainment technique can be used in those cases where the eutectics are situated very close to the racemate. This underscores the value of systematic searches for derivatives that form conglomerates or at least racemic compounds whose eutectics are close to that of the racemate.

Another further way of purification is the formation of diastereomeric salts. However, partial solid solution are often observed and it is difficult to achieve high purity. Resolution via diastereomeric salt formation based on a part of the DSC curve has been discussed (102).

The change from racemates to enantiomers has implication in the galenical formulations. Propanolol-base enantiomer has a better skin permeation than racemate, what was explained by a lowering of the melting point (103). The stereospecific preformulation of ibuprofen has also been discussed. The theoretical phase diagram has been calculated from the DSC curves of the (+) enantiomer and of the racemate by using the equations of Schröder–Van Laar and Prigogine–Defay equations. Experimental data confirm the calculated data (104, 105).

Fig. 16 Phase diagrams for enantiomers: (a) conglomerate, (b) and (c) racemic compound, (d) solid solution.

The low melting point of the enantiomer may have implications of the pharmaceutical process. Relationships between physical properties and crystal structures of chiral drugs have been discussed (106).

APPLICATION OF THERMAL TECHNIQUES FOR THE DRUG PRODUCT: PREFORMULATION, PROCESSING, AND AGING

The preformulation includes the choice of the salt form and of the polymorph of the drug substance. Melting points, solubilities, dissolution, hygroscopicity, stability, feasibility, processability, and polymorphic behavior have to be considered. The second step is to study the behavior of the drug substance with excipients (107).

Excipients

The use of thermal analysis techniques for pharmaceuticals implies the knowledge of the thermal behavior of the excipients. A great number of publications deal with polymorphic behavior of excipients and especially with the amorphous forms as prerequisite knowledge for freeze drying and milling processes.

Lactose exists in two isomeric forms α and β . It is possible to obtain the α -monohydrate, anhydrous crystalline α and β forms, as well as an amorphous form. The pharmaceutical properties of these various types are different. The hardness of tablets obtained using amorphous lactose produced by lyophilization is 10 times that obtained using crystalline forms. During milling, it has been observed that the monohydrate loses part of its water of crystallization and of its crystallinity. Heat treatment of different lactoses has permitted the discovery of an anhydrous, unstable α form and a crystal containing α and β in the ratio 1:1. Under the influence of high degrees of humidity, amorphous lactose crystallizes and anhydrous forms tend to reconvert to the monohydrate (68, 108, 109).

The thermal analysis studies of different forms of sorbitol, mannitol, glucose, magnesium stearate are reviewed in (68). Mono-, di-, and trihydrate of magnesium stearate as well as the amorphous form may be found. According to Wada et al. (110), thermal analysis is the most appropriate method for characterization of magnesium stearate.

Thermal analysis are widely used for polymers and copolymers analysis (4). Glass transitions, melting, and decomposition processes are analyzed. Since the glass transition temperature T_g is marked by changes in

the thermal capacity, expansion coefficient, and rigidity, TMA technique as well as DSC may be used. T_g increases with molecular mass up to certain values. Plasticizers and water depress this temperature. Thermal stability and influence of antioxidants and fillers may be analyzed by TG or DSC, under oxygen.

The compatibility of polymers in blends is tested by comparing DSC curves of the components. Immiscible crystalline blends such as polyethylene–polypropylene show the DSC peaks of polyethylene and polypropylene. Immiscible amorphous blends exhibit two glass transitions; in miscible blends a new glass point is observed. Partially miscible blends have two glass points situated between the glass points of each polymer. Different equations such as Gordon–Taylor express the relation between the new glass transition T_g and the glass transition points T_{g1} and T_{g2} of components. W_1 and W_2 are the weight fractions and K is the ratio $\Delta C_{p2}/\Delta C_{p1}$.

$$T_g = W_1 T_{g1} + K W_2 T_{g2} / W_1 + K W_2$$

The polymers mostly used in pharmaceutical packaging are polyethylene, polypropylene, PVC, polyamide, polystyrol, nylon, cellulose acetate, polyethylene terephthalate, and blends thereof. Copolymers and rubbers are also used. The DSC melting curve of polyethylene used for packaging purposes is characteristic. Low- and high-density polyethylene are differentiated by their melting points (111). Melting point and density of polyethylene are linearly correlated (112). Crystallinity may be determined as described above for amorphous state.

Polyethylene glycols (PEG) have been intensively characterized by thermal analytic methods. The melting points of PEG increase with the molecular weight and decreases with the content of water as a result of eutectic formation (10). Corrigan (113) studied the different DSC peaks of PEG: Once folded chain crystals and extended chain crystals are present in PEG 6000, which results in two DSC peaks. In PEG of higher molecular mass, only folded chain crystals are present. Lower molecular mass PEG contain only extended chain crystals. Craig reviewed the thermal studies of PEG, including properties in aqueous solutions (114, 115). Phase diagram of PEG 4000 was recently discussed (116). Higher molecular mass PEG are generally used in solid dispersion systems and their melting behavior is relevant for the temperature of galenical preparation (5, 117).

Glass transitions of polyvinylpyrrolidones of different molecular weight may be used as identity (10, 118). Water depresses the glass transitions and effects the physical properties of polyvinylpyrrolidone, as demonstrated by Tan and Challa (119).

Fig. 17 Influence of the water content on the glass transition temperature of HPMC 4000 measured by DSC in sealed pans.

A large number of cellulose derivatives have been studied for food as well as for pharmaceutical applications (120–123). The measurement of the glass transition is often difficult due to the broad endotherm of dehydration of water. Figure 17 shows the effect of water on the depression of the glass transition of hydroxypropyl methylcellulose HPMC4000.

Film coating processes need the knowledge of the glass transitions for a proper film. Ethylcellulose, cellulose phthalate, polyvinylalcohols, polymethyl methacrylates have been studied and the critical parameters for film formation discussed (124–126).

Fig. 18 DSC curve of L-poly(lactic acid) after quenching from the melt. (From Ref. 10.)

Polysaccharides and water interaction are especially studied for their use in spray-dried products in food and in biotechnology (127–129).

Biodegradable polymers can be crystalline or amorphous. Poly-L-lactic and D,L-poly(lactic acids) have been studied by Pitt and Gu (130). Figure 18 deals with the second run of poly-L-lactic acid after quenching. The glass transition is followed by crystallization, the melting of the crystalline form. Aging and crystallinity of biodegradable polymers have been studied by Akhtar et al. (131). TG is useful for the determination of the entrapped solvent (often methylene chloride) and of moisture (5, 10). Microspheres containing biodegradable polymers are intensely analyzed by thermal analysis techniques allowing both the glass transition point of the polymer and the physico-characterization of the drug substance to be analyzed; thermal techniques generally with electron microscopy are used for the optimization of the drug loading and of the process (132). The physical aging of the polymer can be assessed in DSC by the amplitude associated with the glass transition of the matrix. This relaxation energy increases with aging. Rosilio studied the progesterone poly(D,L-lactide-co-glycolide) microspheres. Aging acts on the solid state of the drug substance loaded. Different polymorphs are obtained, depending on the copolymer composition (133).

Phase Diagrams

The thermodynamic phase diagrams are the basis for understanding DSC curves of formulation: eutectics, solid solutions, eutectics with partial solid solutions, and compound formation with congruent or incongruent melting. Figure 19 exemplifies the building of the phase diagram of propyphenazone and butesamide, using the DSC curves. In order to save the number of DSC scans, theoretical curves can be added (134). Such phase diagram was performed between a drug substance and stearic acid: no formation of the salt was observed (13). Recently thermal analysis has been used for the complex phase diagram of propanol/oleic acid for which the salt and a mesomorphic phase have been found (135).

DSC was proposed for compatibility studies comparing DSC curves of components and mixtures. Unfortunately some misinterpretation may occur. DSC curves can only reflect physical behavior. The formation of eutectic is not an incompatibility. Furthermore, water generally is not present in the mixtures at the temperatures of the melting peaks. Giron et al. (9) performed the DSC curves of a drug substance and several excipients, the initial DSC curves of the mixtures and the DSC curves of the mixtures after 1 month at 50°C/<30% RH and 50°C/75% RH. Chromatography was used for the chemical analysis

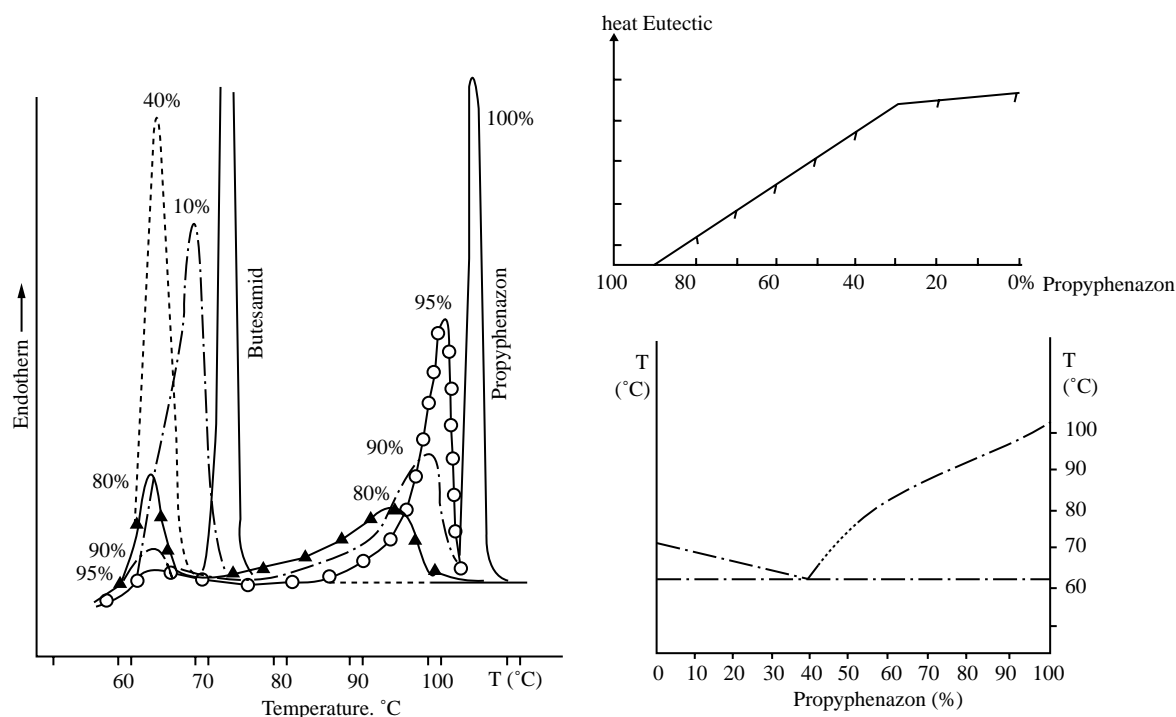

Fig. 19 Example of building a phase diagram by DSC of propyphenazone and butesamide. (From Ref. 6.)

of the drug. Figure 20 shows the comparison of the DSC curves of the mixtures. The effect of the humidity on the degradation is very striking: The drug substance is completely decomposed with calcium sulfate, avicel, and stearic acid. For talc and dicalcium phosphate, there is no degradation. The observation of the initial DSC curves for the five excipients would have wrongly given the conclusion to the same compatibility.

For such compatibility studies, isothermal microcalorimetry has been suggested (e.g., Ref. 136).

The DSC study of mixtures of drug and excipients is very useful, for the information gained (e.g., if the eutectic melts at ambient temperature). In other cases, one may target interaction with excipients as it is the case of solid dispersions, solid solutions, or complex formation. The choice of the carrier defines the characteristics of dissolution of the dispersed drug. Poorly water-soluble active ingredients are combined with water-soluble carriers in order to increase the dissolution of the active ingredient. A good water-soluble drug combined with a slightly soluble carrier leads to a retardation of drug release from the matrix. For reviews on solid dispersions, see Refs. 5 and 137. For the development of solid dispersions, the method of preparation, the type of systems, the dissolution characteristics, and the aging problems should be considered. DSC is appropriate for the study of solid dispersions by comparing DSC curves of pure compounds, of physical mixtures or

melted mixtures to the DSC curve of the solid dispersion. TG, X-Ray diffraction, and hyphenated techniques are good complements. The transitions observed are those transitions expected from the phase diagrams, or the amorphous state with glass transition or very often new metastable forms of drug substance as well as metastable forms of excipients.

The phase diagram given in Fig. 21 for darodipine–polyethylene glycol 6000 results from DSC experiments carried out by two techniques (10). The DSC of physical mixtures obtained by grinding were scanned just after the end of melting. After cooling a second scan at 5 K min^{-1} was performed. In the second technique the mixtures were dissolved in methanol and the solvent evaporated. With both techniques, the same results were obtained.

The knowledge of the phase diagram allows the choice of the temperature of the process. It can be suitable to choose higher loading than the eutectic composition. Once the solid dispersion manufactured and milled, DSC is very advantageous for checking the batch reproducibility or the stability behavior by the measurement of the melting enthalpy of the eutectic. For a solid dispersion with 40% darodipine, a standard deviation of 1.4% for the melting point of the eutectic located at 58°C and 2.4% for the heat of eutectic of 27 cal g^{-1} was found.

PEG used for solid dispersion vary from molecular weight 1000 to molecular weight 20,000. PEG of lower

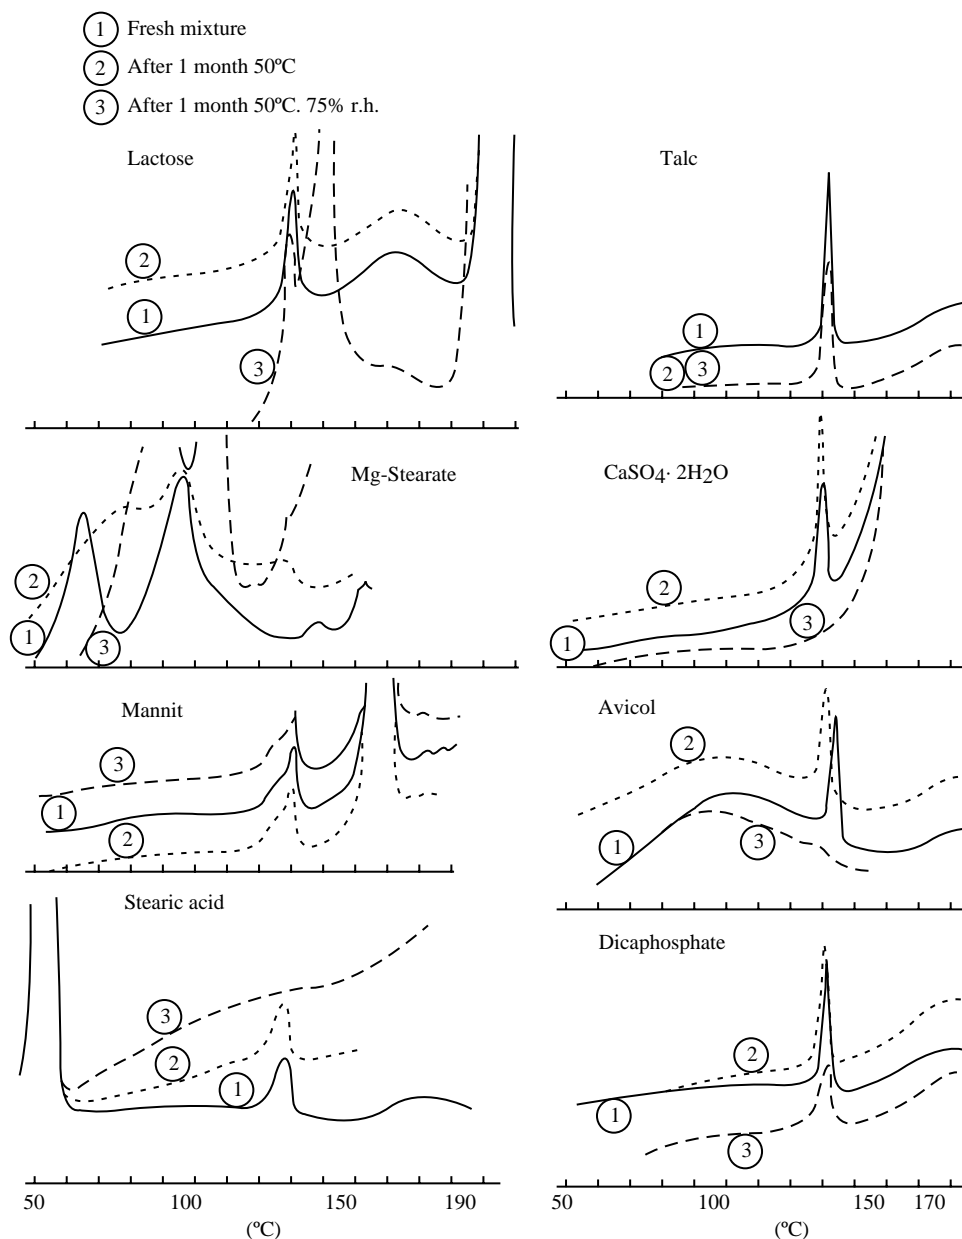

Fig. 20 DSC curves of 10% drug substance with excipients: 1: Original curves; 2: curves after 1 month at 50°C/<30% RH; and 3: 50°C/75% RH. The initial DSC curves suggest an incompatibility only with mannitol and magnesium stearate. The DSC curves (curves 3) after storage at 50°C/75% RH allow the differentiation of the excipients: degradation with stearic acid, calcium sulfate dihydrate, and avicel.

molecular weight are liquid and therefore not suitable. The quality mostly used are PEG 4000 and PEG 6000. The composition of the eutectic of most drug substances lies in small concentration of drug substance. Some monotectics (0% drug substance) have been described. The highest amount of drug is obtained with glutethimide with an eutectic composition of 32% (5).

Solid solutions: The drug and the carrier are miscible in the solid state. Polyvinylpyrrolidones (PVP) with different molecular weights dissolve drug substances such as diazepam (138) through hydrophobic interactions. The disparition of the DSC peak of the drug substance demonstrates the formation of the solid solution.

Fig. 21 Phase diagram of a solid dispersion of darodipine-PEG 6000.

Drug substance and carrier can be both in the glassy state. Total miscibility, partial miscibility, or total immiscibility has been observed. This type of system is very sensitive to temperature and moisture and crystallizations are often observed after long storage.

New derivatives of starch, mainly cyclodextrins (139) which forms inclusion compounds, are best carriers for the monitoring of the dissolution characteristics of the drug. These cyclic oligosaccharides contain six (α -CyD), seven (β -CyD), and eight (γ -CyD) α -(1,4)-linked glucose units. A great number of chemically modified cyclodextrins have been manufactured in the last decade. Complexes are formed through inclusion in the cavity or through interactions with chemical groups. In order to obtain complexation, the compounds have to bind a complex first in solution. From the usual methods of preparation, kneading, coprecipitation, freeze drying, or spray drying, often the spray-drying technique gives the best results.

Giordano et al. (140) suggested a method of calculation of the ratio guest/host. They performed DSC analysis of dispersions of different compositions with an excess of the guest molecule. The remaining energy in the melting peak of the guest molecule allows the calculation of the amount of free drug. They plot this amount for different compositions versus the total guest fraction and

compared the plot obtained with the theoretical plots for ratios 1:1, 1:2, 1:3.

In most cases the DSC peak of the drug substance disappears and no new peak is observed. With hydrocortisone butyrate (141), a new peak corresponding to the complex has been observed. For this drug, the complexation increases in the order α -CyD, β -CyD, γ -CyD, and dimethyl- β -CyD. Thermogravimetry analysis has also been used (142). The temperatures of vaporization, sublimation, or degradation of the drugs are displaced to higher temperatures, due to the complexation.

Analysis of the Drug Product

If the components are not miscible in the solid and the liquid states, their DSC peaks remain unchanged. This allows to identify components of the drug product, to follow aging problems with polymorphism and in favourable cases to quantify the drug substance and the excipients (11, 20, 143, 144).

Fatty Acids and Glycerides Derivatives

Most fats and similar compounds show polymorphism behavior, including fatty acids, fatty alcohols,

Fig. 22 DSC curves for the monitoring of fractionation of a liquid excipient. Scan rate 20 K min⁻¹.

Fig. 23 Aging of precirrol.

cetostearyl alcohols, glycerides, oils, hydrogenated or transesterified oils, and suppositories (145). This polymorphic behavior is characterized by change of melting by aging, giving rise to hardening effects of suppositories and precipitations of liquid excipients that are complex mixtures of glycerides. Examples of aging problems are given in (10). Fig. 22 is an example of the control of the fractionation of a liquid excipient, using DSC. Aging of the precirrol excipient is demonstrated in Fig. 23. Sub ambient DSC was also used for the preformulations of microemulsions (11–13). The solid fat index, calculated as a percentage of the solid as function of the temperature, is very valuable for the evaluation of suppositories (146). Analysis of the drug is also possible. Chemical reaction was observed for aminophylline (147). Since most fatty acid derivatives are unsaturated, they are very sensitive to oxidation. The oxidability and the influence of antioxidants can be measured by DSC and TG, comparing the starting of the degradation (148).

Fig. 24 Phase diagram of water and amorphous substance during freeze drying.

Interaction with Water

The phase diagrams of drug substance and excipients with water as well as the study of the temperature of glass transition (see Fig. 24) are the basis of the choice of the conditions of freeze-dried or spray-dried formulations (149–152). The lyophilizates are well characterized by DSC and TG. The polymorphic behavior of all components can be studied by thermal techniques. For proteins, it is suitable to have excipients in the formulation that remains amorphous. Trehalose was found to be a very efficient lyoprotectant (153).

Freezable water is determined by the measurement of the melting peak of ice. This technique is currently applied for creams, and gels (154, 155). Examples of the melting peak of freezable water are given in Fig. 25. Swelling properties of modified release matrices and their interaction during dissolution have been studied (156, 157).

Monoglycerides–water systems have been characterized (158). Three classes of phases (lamellar, cubic, and hexagonal) have been determined. Water/oil systems and their aging on the phase transitions have been studied using DSC (159, 160). Thermogravimetry can be successfully used additionally (161).

Liposomes are multilayered vesicles consisting of concentric bilayers of phospholipids interdispersed with

Fig. 25 Determination of freezable water, using the melting peak of ice. (a) Methocel K15 M, (b) cetyl palmitate, and (c) pharmaceutical gel.

aqueous phases. In aqueous media, the phospholipids undergo gel, liquid crystalline transitions easy to detect by DSC. The study of the change of these transitions, temperature, peak width, and energy allows to characterize the hydrated phospholipid bilayers and to study the liposome formation with drugs (162–164). Drug targeting studies with phospholipids membranes have been proposed using DSC technique (165).

CONCLUSION

Thermal analysis methods are widely used in all fields of pharmaceuticals. They are unique for the characterization of single compounds. The information correlated with the thermodynamic phase diagrams is extremely helpful for rational preformulation and development of new delivery systems. Very rapid and requiring only very small samples of material, these methods are applicable in development and also in production for quality control. The combination with spectroscopic and crystallographic data will allow better insight in complex phase changes behavior.

TITRIMETRY

Vesa Virtanen

Orion Pharma, Kuopio, Finland

DEFINITION OF TERMS

Titrimetry or titrimetric analysis is any method of quantitative chemical analysis in which the amount of a substance is determined by measuring the volume that it occupies or the volume of a second substance that is needed to react completely with the substance being determined. Titration is a process of chemical analysis in which the quantity of some constituents of a sample is determined by adding to the measured sample an exactly known quantity of another substance with which the desired constituent reacts in a definite, known proportion. The reagent of exactly known composition used in a titration is called a standard solution.

The goal of titration is the equivalence point, where the addition of standard solution in an amount that is chemically equivalent to the substance with which it reacts. In fact, its position can be estimated only by observing physical changes associated with it in the solution. These changes manifest themselves at the endpoint of the titration.

An indicator is a supplementary chemical compound that exhibits a change in color as a result of concentration changes occurring near the equivalence point.

PRECIPITATION TITRATIONS

In these titrations, the determination of the substance is effected by precipitating it in the form of an "insoluble" compound of known composition. The equivalence point is reached when sufficient reagent to complete precipitation has been added. In practice, the insoluble reaction product formed will be very slightly soluble and to an extent that depends on the amount of solvent present as well as on the nature and amounts of other ions and compounds present.

In the simplest general case of a slightly soluble salt (AB) formed by the reaction of the oppositely charged univalent anion (A^-) and cation (B^+) of two soluble salts:

where K_{ppn} is the precipitation constant. Assuming that interferences are small enough to be neglected, the concentration of the insoluble salt AB may be regarded as being constant:

$$K_{ppn}[AB] = [A^-][B^+] = \text{constant} = S_{AB}$$

where the constant S is the solubility product. If the solution is pure, equivalent concentrations of A^- and B^+ will be present, and therefore:

$$[A^-] = [B^+] \text{ or } [A^-]^2 = [B^+]^2 = S_{AB}.$$

In this case, if the product $[A^-][B^+]$ exceeds $(S_{AB})^{0.5}$, the solution is saturated with respect to AB, and this substance separates as a precipitate (1).

Titration Curves

Titration curves are based on the negative logarithm (to the base 10) of the molar concentration of the species; p -values or p -functions are useful for deducing the properties required of an indicator as well as the titration error that its use is likely to cause.

The general shape of a titration curve for the precipitation titration of a solution containing one anion, Cl^- , is shown in Fig. 1. Curves plotted from calculated pX values are always symmetrical. A curve plotted by using experimentally obtained values for $[Cl^-]$ is not symmetrical. The lack of symmetry is due to those ions that are being adsorbed in excess by the precipitate in different amounts. This fact is not taken into account in theoretical calculations. Accurate precipitation titrimetry requires a long, steep AB section because the length of AB depends on the initial concentrations of the reactants and the value of the solubility product of the compound precipitated. An increase in analyte and reagent concentration enhances the change in pX in the equivalence point region.

Precipitation titrations can be extended to mixtures that form precipitates of different solubilities. The titration curve in Fig. 2 for a chloride/iodide mixture is a composite of the individual curves for the two anionic species. Because silver iodide has a much lower solubility than does silver chloride, the initial additions of the reagent

Fig. 1 A theoretical precipitation titration curve.

result exclusively in formation of iodide. Thus, two equivalence points are evident.

Endpoint Detection

The stoichiometric equivalence point should be immediately detectable. This usually requires a large change in some physical or chemical property of the solution. This point in the reaction is often located by means of a

Fig. 2 Titration curve of solution with iodide and chloride.

secondary system, which provides an observable endpoint. This secondary system must be reproducible, clearly identifiable, and ideally coincident with the stoichiometric equivalence point. Because coincidence is not always achieved, the difference between the endpoint and the equivalence point should be easily measurable. Often, so-called blank solution is used for this correction. A chemical indicator produces a visually detectable change in the solution, usually color or turbidity, or may form another precipitate that has a distinctive color. The indicator functions by reacting competitively with one of the reactants or products of the titration and, therefore, its concentration must be kept low, favoring an intense color at the endpoint. For some determinations, an electrochemical sensor provides an accurate way of locating the equivalence point.

The formation of a second, highly colored precipitate is the basis of the Mohr method of endpoint detection. Chloride and bromide ions are titrated with standard silver nitrate using chromate ion as indicator, the endpoint being indicated by the appearance of brick-red silver chromate (2).

Because silver chromate is more soluble, the K_{sp} value (soluble product constant) of silver chromate is not exceeded until the precipitation of Cl^- is complete. The endpoint can be corrected by using the Mohr method to standardize the silver nitrate solution against pure sodium chloride.

The Volhard method of endpoint detection involves using Fe^{3+} ions as the indicator (3). This procedure requires a suitably acidic solution to prevent precipitation of iron(III) as the hydrated oxide. It has the disadvantage that it is useful only for the reaction:

After the first excess of thiocyanate ions is added, the indicator reaction is:

This means that to determine halide ion (except F^-) back titration is required. In this case, a measured aliquot of standard silver nitrate solution is added to the sample, and the excess silver ion is determined by back-titration with a standard thiocyanate solution.

An adsorption indicator is typically an organic dye, such as fluorescein and its derivatives. Most adsorption indicators are weak acids. Their use is thus confined to basic, neutral, or slightly acidic solutions in which

Fig. 3 A conductivity curve for precipitation titration.

the indicator exists predominantly as the anion. Some cationic adsorption indicators are suitable for titrations in strongly acidic solutions. In this case, adsorption of the dye and coloration of the precipitate occur if the precipitate particles possess a negative charge.

Because the total amount of ions in solution decreases as the analyte is precipitated, the conductance of the solution must decrease. For an accurate result, the plot of conductivity against volume of titrant added has the characteristics shown in Fig. 3. This technique is suitable for both dilute and concentrated solutions as well as for colored solutions.

The electromotoric force (emf) of a cell depends on the ionic concentration of the solutions. To locate the equivalence point, the variation in emf is monitored as the concentration of the analyte changes. When the measured emf is plotted against the total volume of titrant added, the curve produced is similar to that of a titration curve Fig. 4. This technique has all the advantages of the conductometric method and gives an experimental curve from which the endpoint can be detected accurately.

Applications

Most applications of precipitation titrations are based on the use of a standard silver nitrate solution and are therefore sometimes called argentometric methods (Table 1).

Fig. 4 Titration curves for a mixture of halides.

NEUTRALIZATION TITRATIONS

Acid–Base Equilibria

Aqueous solutions always contain hydronium ions as well as hydroxide ions as a consequence of the dissociation of water:

Certain solutes cause changes in the concentrations of the two species, often with profound effect on the chemical characteristics of the solution.

Application of the mass law to the dissociation of water leads to $K_w = [\text{H}_3\text{O}^+][\text{OH}^-]$, where K_w is called the ion-product constant for water. At 25°C the ion-product constant has the numerical value of $1.0 \times 10^{-14} \text{ mole}^2/\text{L}^2$. In pure water, the concentrations of hydronium and hydroxide ions are identical, and pure water is neutral.

A useful relationship is obtained from the negative logarithm of both sides of the ion-product constant expression. Thus:

$$\begin{aligned} -\log K_w &= -\log[\text{H}_3\text{O}^+][\text{OH}^-] \\ &= -\log[\text{H}_3\text{O}^+] - \log[\text{OH}^-] \end{aligned}$$

Table 1 Typical applications of precipitation titrations

Analyte	Titrant	Endpoint Detection
Cl^- , Br^- , I^-	Ag^+	Potentiometric
Cl^- , Br^- , I^-	Ag^+	Precipitate
Ag^+	SCN	Fe(III), potentiometric
Cl^- , Br^-	$\text{Hg}(\text{NO}_3)_2$	Precipitate
SO_4^{2-} , MoO_4^{2-}	$\text{Pb}(\text{NO}_3)_2$	Precipitate

from which it follows that:

$$pK_w = -\log K_w = pH + pOH$$

where pK_w represents the negative logarithm of the ion-product constant of water. At 25°C, pK_w is 14; that is, $pH + pOH = 14.00$.

Buffer Solutions

A buffer solution resists changes in pH as a result of dilution or small additions of acids or bases. The most effective buffer solutions contain high and approximately equal concentrations of a conjugate acid–base pair. The resistance of buffer mixtures to pH is changed by adding acids or bases. The ability of a buffer to prevent a significant change in pH is directly related to the total concentration of the buffering species and their concentration ratios. The buffer capacity of a solution is defined as the number of equivalents of strong acid or base needed to cause 1.00 L of the buffer to undergo a 1.00-unit change in pH (4).

Acid–Base Indicators

Endpoint detection in a neutralization titration is ordinarily based on the abrupt change in pH that occurs near the equivalence point. A noninstrumental method of pH measurement much used in simple titrations uses indicators. These are generally organic dyes, or weak acids or bases, that on dissociation or association undergo internal structural changes at or near the equivalence point of the neutralization, resulting in a color change.

A list of some compounds possessing acid-base indicator properties is shown in Table 2. Ethanol is the common solvent for indicator solutions.

Titration curves of simple systems

When both reagent and analyte are strong, the net neutralization reaction can be expressed as follows:

The hydronium ions in an aqueous solution of a strong acid derive from two sources: the reaction of the solute with water and the dissociation of water itself.

Titration of a strong acid with a strong alkali starts with pure acid in the start that is gradually diluted, changing increasingly to a neutral salt until only neutral salt remains at the equivalence point. Immediately beyond the equivalence point, the amount of strong alkali increases. The change in pH near the equivalence point will be sharp and large. This may or may not be at pH 7, depending on

Table 2 Some acid-base indicators

Indicator	pH range	Color change
Cresol red	0.2–1.8	red–yellow
Thymol blue	1.2–2.8	red–yellow
	8.0–9.6	yellow–blue
Bromophenol blue	3.0–4.6	yellow–blue
Methyl yellow	2.9–4.0	red–yellow
Methyl orange	3.1–4.4	red–orange
Congo red	3.0–5.0	blue–red
Bromocresol green	3.8–5.4	yellow–blue
Methyl red	4.2–6.3	red–blue
Bromocresol purple	5.2–6.8	yellow–purple
Bromothymol blue	6.0–7.6	yellow–blue
Phenol red	6.8–8.4	yellow–red
Cresol purple	7.6–9.2	yellow–purple
Thymol blue	8.0–9.6	yellow–blue
Phenolphthalein	8.3–10.0	colorless–red
Thymolphthalein	9.3–10.5	colorless–blue
Alizarin yellow GG	10–12	colorless–yellow

the degree of ionization of the acid and base, that is, their strengths as acid or base.

Titration of a weak acid such as acetic acid against strong base gives a titration curve as that shown in Fig. 5. At first, partly ionized acid is present owing to a pH too high for a strong acid. As neutralization continues, more acid ionizes and mainly ionized acid and salt are present. Therefore, the pH changes gradually; this is called the buffer effect. If a strong acid is titrated with a weak base such as ammonia, the converse occurs.

Fig. 5 A weak acid-strong base titration curve.

When a weak acid is titrated with a weak base, the titration curve shows a continuously and gradually changing pH with the addition of base. No region with a sharp shift in pH is obtained for small additions of titrant. If a sharp shift occurs, it is still less than 2 pH units and not detectable by indicators. On both sides of the equivalence point, buffers are present, and at the equivalence point, the pH depends on the relative strengths of acid and base.

Titration curves of complex systems

Complex systems include solutions containing two acids or bases, which contain or consume two or more protons, and amphiprotic substances that act as both acids and bases. A characteristic of all such systems is that two or more equilibria must be considered in describing their behavior. As a consequence, the techniques for pH data derivation are often more complex than for simple systems.

A titration curve for the titration of weak and strong acids with strong base is shown in Fig. 6. The stronger acid is neutralized first, along with some of the weaker acid. As a result, a curve more sloping is obtained. The sharp pH change of the strong acid is still obtained, although the weaker acid interferes. After all the strong acid has gone (point A), the weaker acid is titrated (point B).

Compounds with two or more acidic or basic functional groups will yield multiple endpoints in a titration, provided the acidic or basic groups differ sufficiently in strength. Computational techniques permit the derivation of reasonably accurate theoretical titration curves for polyprotic acids or bases, provided the ratio K_1/K_2 is above 103. K_1 and K_2 are dissociation constants. The titration curve of a dibasic weak acid with NaOH resembles that shown in Fig. 6.

Fig. 6 Titration of a mixture of a strong and a weak acid with alkali.

The derivation of a titration curve for a polyfunctional base is similar to the previous one for acid.

Amphiprotic substance, when dissolved in a suitable solvent, behaves both as a weak acid and as a weak base. If either its acidic or its basic character predominates sufficiently, titration of the species with a strong base or a strong acid may be feasible.

Applications in Aqueous Media

Several important elements that occur in organic and biological systems are conveniently determined by methods that involve an acid-base titration as the final step. Generally, these elements are nonmetallic such as carbon, nitrogen, chlorine, bromine, sulfur, phosphorus, and fluorine. However, in addition, similar methods exist for several less commonly encountered species. In each case, the element is converted to an inorganic acid or base that can be titrated.

Numerous inorganic species can be determined by titration with strong acids or bases. For example, ammonium salts are determined by conversion to ammonia with strong base and distillation in the Kjeldahl apparatus. Also, inorganic nitrates and nitrites can be determined using Kjeldahl method (5) by reducing these species to ammonium ion.

Carboxylic and sulfonic acid groups impart acidity to organic compounds. Most carboxylic acids and sulfuric acids are readily dissolved in water, and their titration with a base is straightforward. If solubility in water is not sufficient, the acid can be dissolved in ethanol and titrated with aqueous base. Aliphatic amines and many saturated cyclic amines can be titrated directly with a solution of a strong acid. Esters are determined by saponification with a measured quantity of standard base. The excess base is titrated with standard acid.

Many aldehydes and ketones can be assayed with the aid of a solution of hydroxylamine hydrochloride. The liberated hydrochloric acid is titrated with base. The total salt content of a solution is determined by converting the salt to an equivalent amount of an acid or a base by passage through a column packed with an ion-exchange resin and then titrated with either base or acid, respectively.

Applications in Nonaqueous Media

Many useful titrations can be performed in glacial acetic acid, which is used widely for the titration of aromatic amines, amides, ureas, and other weak nitrogen bases. Direct titration of most amino acids with a standard acid can be performed in glacial acetic acid.

Basic solvents such as ethylenediamine, dimethylformamide, pyridine, and dimethylsulfoxide can be used for acids that are too weak to be titrated in water. Amine salts, inorganic salts, carboxylic acids, phenols, and imides are soluble in ethylenediamine, where they exhibit enhanced acidic characteristics.

Many sulfa drugs such as sulfanilamide, sulfathiazole, and sulfathalidine can be titrated in ethyleneamine with tetrabutylammonium hydroxide. The ability of dimethylformamide to dissolve salts, polymers, and many organic compounds accounts for its wide use as a titration solvent. Inert solvents such as acetone can be used for titration of acids, acetonitrile for both acids and bases, and ethyl acetate for amines. A suitable nonaqueous medium such as methyl isobutyl ketone makes it possible to discriminate among various mineral acids that are not leveled by the solvent as they are in water.

OXIDATION-REDUCTION TITRATIONS

Equilibrium

Oxidation of a substance (element or a compound) involves the loss of electrons. Conversely, reduction of a substance involves the gain of electrons. Thus, in oxidation-reduction system, electron transfer occurs.

In titration of iron(II) with cerium(IV):

equilibrium is attained after each addition of titrant. After the first addition of cerium(IV), all four species will be present in the solution in amounts dictated by the equilibrium constant of the reaction. At chemical equilibrium of an oxidation-reduction system, the electrode potentials E for the two half-reactions are identical. Thus, at any point in the titration:

$$E_{\text{Ce}^{4+}} = E_{\text{Fe}^{2+}} = E_{\text{system}}$$

If the solution contains a reversible oxidation-reduction indicator as well, its potential must be the same as that for the system:

$$E_{\text{In}} = E_{\text{Ce}^{4+}} = E_{\text{Fe}^{2+}} = E_{\text{system}}$$

Titration Curves

The potential of a system can be measured experimentally by determining the emf of a suitable cell. Thus, for the titration of iron(II) with cerium(IV), the cell is:

Fig. 7 Titration curve for iron(II) with cerium(IV).

The potential of the platinum electrode versus a saturated calomel electrode (SCE) is determined by the affinity of Fe^{3+} for electrons:

and that of Ce^{4+} :

In deriving Esystem data for a titration curve, either $E_{\text{Ce}^{4+}}$ or $E_{\text{Fe}^{3+}}$ can be used. Short of the equivalence point, the concentration of cerium(IV) is vanishingly small. The concentrations of iron(II), iron(III), and cerium(III) can be calculated from the amount of titrant added.

Applying the Nernst equation for the iron(III)/iron(II) couple gives a value for the potential of the system directly. Using the couple cerium(IV)/cerium(III) would give the same answer, but it would first be necessary to calculate a value for the concentration of cerium(IV), which in turn would require evaluation of the equilibrium constant for the reaction.

As shown in Fig. 7 there is a rapid change in the value of E as the titration is proceeded through the endpoint. In fact, the titration curve has the same general form as that of an acid-base titration. An exact value for the endpoint can be calculated using the Nernst equations for the half-reactions.

The shape of the curve for an oxidation-reduction titration depends on the nature of the system under consideration. The titration curve in Fig. 7 is symmetric about the equivalence point because the molar ratio of oxidant to reductant is equal to unity. An asymmetrical curve results if the ratio differs from this value. Solutions containing two oxidizing or reducing agents yield titration curves containing two inflection points if the standard

Fig. 8 Titration of iron(II) and titanium(III) with cerium(IV).

potentials for the two species are different by more than approximately 0.2 V. Fig. 8 shows the titration curve for a mixture of iron(II) and titanium(III) with cerium(IV). The first additions of cerium are used by more readily oxidized titanium(III) ion, thus, the first step in the titration curve corresponds to titanium and the second to iron.

Oxidation–Reduction Indicators

Specific indicators owe their behavior to a reaction with one of the participants in the titration. The best-known specific indicator is starch, which forms a dark blue complex with triiodide ion. Also, potassium thiocyanate is

used as a specific indicator, for example, in titration of iron(III) with solutions of titanium(III) sulfate.

Oxidation–reduction indicators

A redox indicator is essentially a compound that has oxidized and reduced forms with different, and preferably intense, colors (Table 3). The half-reaction responsible for color change in a typical oxidation–reduction indicator can be written as:

Applications

Standard oxidants

The powerful oxidant potassium permanganate, KMnO_4 , is a widely used oxidizing agent. It is most commonly used with solutions that are 0.1 *N* or greater in mineral acid. Under those conditions, the product is manganese(II):

However, the tendency of permanganate to oxidize chloride ion is a disadvantage because hydrochloric acid is such a useful solvent and, furthermore, KMnO_4 solutions have limited stability.

For example, determinations of Sn, H_2O_2 , Fe, V, Mo, W, U, Ti, Mg, Ca, Zn, Co, Pb, Ag, K, Na, and HNO_2 potassium permanganate are used as oxidizing agents.

A sulfuric acid solution of cerium(IV) is nearly as potent an oxidizing reagent as is permanganate and can be substituted for the latter in most of the applications described with potassium permanganate. Cerium(IV) does not oxidize chloride ion at a detectable rate as does permanganate, and the reagent is indefinitely stable. On the other hand, the color of cerium(IV) is not sufficiently intense to serve as an indicator. In

Table 3 Some redox indicators

Indicator	Color change oxidized-reduced	Transition potential, V
Indigomonosulphonate	Blue—colorless	+ 0.26
Phenosafranin	Red—colorless	+ 0.28
Indigotetrasulphonate	Blue—colorless	+ 0.36
Methylene blue	Blue/green—colorless	+ 0.53
Diphenylamine	Violet—colorless	+ 0.76
<i>p</i> -Ethoxychrysoidine	Yellow—red	+ 0.76
Diphenylamine sulfonic acid	Red/purple—colorless	+ 0.85
Eriocaulin A	Red—yellow/green	+ 0.98
1,10-phenanthroline iron(II)	Pale blue—red	+ 1.11
2,3-diphenylamine dicarboxylic acid	Blue/violet—colorless	+ 1.12

addition, the reagent cannot be used in neutral or basic solutions.

Use of potassium dichromate is limited because of its lesser oxidizing strength and slowness of some of its reactions. This technique is used for determination of iron(II), nitrate, chlorate, permanganate, and organic peroxides, among others.

Iodine, a relatively weak oxidant, is used for the selective determination of strong reducing agents. Iodine can be used for determination of As, Sb, Sn, H_2S_2 , SO_2 , $\text{S}_2\text{O}_3^{2-}$, and N_2H_4 , among others. Its great advantage is its ready availability as a sensitive and reversible indicator. Its disadvantages include the low stability of iodine solutions and the incompleteness of reactions between iodine and many reducing agents.

Potassium bromate is a convenient source of bromine in organic analysis. Few organic compounds react sufficiently rapidly for a direct titration, and, thus, a measured excess of the bromate is added to the sample, and after the reaction is complete, the excess bromine is back-titrated with an arsene(III) solution. Some organic compound analyzed using bromine substitution are, for example, phenol, *p*-chlorophenol, salicylic acid, acetylsalicylic acid, *m*-cresol, aniline, sulfanilic acid, and *b*-naphthol. Bromine addition is used most often in the estimation of olefinic unsaturation in fats, oils, and petroleum products.

Reductants

Because of the readiness of reducing agents to react with atmospheric oxygen, the titrations must be carried out in and the reagents must be stored under an inert atmosphere. Alternatively, a stable standard oxidizing agent can be used for titration of an aliquot of the reductant to determine the current concentration of the reducing agent.

A variety of oxidizing agents such as Cr(VI), Ce(IV), Mo(VI), NO_3^- , NH_2OH , and organic peroxides can be determined by reaction with a measured excess of standard iron(II) solution. Standard potassium dichromate is frequently used for the back-titration.

Iodide ion is a moderately effective reducing agent. In its applications, a standard solution of sodium thiosulfate is used to titrate the iodine liberated by reaction of the analyte with an unmeasured excess of potassium iodide. Some substances determined by using iodometric method are IO_4^- , IO_3^- , BrO_3^- , ClO_3^- , Br_2 , Cl_2O_2 , O_3 , Cu^{2+} , NO_2^- , and organic peroxide.

The water content in solids and many organic acids, alcohols, esters, ethers, anhydrides, and halides can be

determined using Karl–Fischer reagent (6), composed of iodine, sulfur dioxide, pyridine, and methanol.

COMPLEX-FORMATION TITRATIONS

Metal ions can act as electron-pair acceptors, reacting with electron donors to form coordination compounds or complex ions. The donor species, or ligand, must have at least one pair of unshared electrons to form the bond. Remarkable growth in the analytical applications of complex-formation reactions is attributable to a particular class of coordination compounds called chelates. These compounds are made by the reaction of a metal ion and a ligand that contains two or more donor groups. The properties of chelates can differ markedly from the parent cation.

Titration Curves

The data necessary to plot theoretical *p*-functions versus reagent volumes require the use of formation (or stability) constants (Fig. 9). Equilibrium between a metal ion M,

Fig. 9 Curves for complex formation titrations. Titration of the tetradentate ligand D (curve A), bidentate ligand (curve B), and unidentate ligand (curve C).

possessing a coordination number of 4, and the quadridentate ligand D can be represented by:

In similar manner, the equilibrium between M and bidentate B can be represented by:

Overall formation of MB_2 occurs in two steps and involves the intermediate formation of MB:

The formation constants for these individual processes are:

$$K_1 = [MB]/[M][B]$$

and

$$K_2 = [MB_2]/[MB][B]$$

The equilibrium constant for the overall reaction is given by the product of the individual steps:

$$K_{\text{overall}} = [MB_2]/[M][B]^2 = K_1 K_2$$

The complex between M and a simple, unidentate ligand A results in the overall equilibrium:

This process occurs also in a stepwise manner, and the equilibrium constant for the overall reaction is therefore numerically equal to the product of the constants for the four constituent processes.

Endpoint Detection

In some complex-formation titrations, the endpoint is noted by the formation or disappearance of a solid phase. For example, in the titration of cyanide with silver ion, the solution remains clear, but the first excess of silver causes formation of a white solid that marks the endpoint. The electron-donor groups of most common ligands tend to combine not only with metallic ions but also with protons; thus, the equivalence point in a complex-formation titration is often accompanied by a marked change in pH, which can be detected with an acid-base indicator.

Formation or disappearance of a soluble colored complex can also indicate an endpoint. Many reagents that form colored complexes with certain metals have been developed only for use as indicators in these titrations. If

the cation being titrated produces a color with the indicator, the endpoint will be characterized by the disappearance of this color. When the cation does not give a colored complex, a second cation that does is introduced, and the first excess of titrant then decolorizes this complex.

Some Applications

Inorganic complexing reagents such as $Hg(NO_3)_2$, $AgNO_3$, $NiSO_4$ and KCN can be used for complex-formation titrations. Mercury(II) ion forms neutral complexes with most of the anions that precipitate with silver nitrate such as Br^- , Cl^- , SCN^- , CN^- and thiourea.

$AgNO_3$ reacts with CN^- forming $Ag(CN)_2^-$. Iodine used as indicator and endpoint is detected by formation of solid AgI. $NiSO_4$ can also be used for determination of CN^- with AgI as indicator. The endpoint is also detected here by formation of AgI. KCN reacts with Cu^{2+} , Hg^{2+} , and Ni^{2+} forming $Cu(CN)_4$, $Hg(CN)_2$ and $Ni(CN)_4$. Various indicators for endpoint detection can be used (7).

Numerous tertiary amines that also contain carboxylic acid groups form remarkably stable chelates with many metal ions. Ethylenediamine tetra-acetic acid (EDTA) can be used for determination of 40 elements by direct titration using metal-ion indicators for endpoint detection (8). Direct titration procedures are limited to metal ions that react rapidly with EDTA. Back titration procedures are useful for the analysis of cations that form very stable EDTA complexes and for which a satisfactory indicator is not available. EDTA is also used for determining water hardness; the total concentration of calcium and magnesium expressed in terms of the calcium carbonate equivalent.

POTENTIOMETRIC TITRATIONS

In potentiometric titrations, the activity of one species is continuously monitored as it changes during the course of the titration, for example, in the titration:

where silver nitrate is added to aqueous sodium chloride. The change in activity of the Cl^- can be monitored. The potential between the reference electrode and the indicator electrode is usually measured at the start of and after the addition of small amounts of titrant. A reproducible equilibrium is of little concern. Requirements for reference electrodes are greatly relaxed. In potentiometric titrations, accuracy is higher than that in direct potentiometric measurements because measured potentials are used to

Fig. 10 Potentiometric titration curves.

detect rapid changes in activity that occur at the equivalence point of the titration. The change in emf versus titration volume is more interesting than the absolute value of the emf. In potentiometric titrations, the influence of liquid-junction potentials and activity coefficients is minimized. The acid and alkali errors of the glass electrode occur at extremes of pH and have little effect near the interesting equivalence point.

Titration Curves and Endpoint Detection

In potentiometric titrations, the titration curve can be followed point by point, plotting as the ordinate successive values of the cell emf versus the corresponding volume of titrant added as the abscissa (Fig. 10). The titrant should be added in the smallest accurately measurable increments that provide an adequate density of points, particularly in the vicinity of the equivalence point. The greatest change in emf occurs around the equivalence point. The most straightforward method takes the midpoint in the steeply rising portion of the curve as the endpoint.

A second approach is to calculate the change in potential-per-unit change in volume in reagent ($\Delta E/\Delta V$). By inspection, the endpoint can be located from the inflection point of the titration curve. This is the point that corresponds to the maximum rate of change of cell emf per unit volume of titrant added (usually 0.05 or 0.1 mL). The first-derivative method is based on the sigmoid shaped curve.

Fig. 11 Gran's plot for a potentiometric titration.

The second-derivative method is an extension of the first-derivative method. The second-derivative of the data changes sign at the point of inflection in the titration curve. This change is often used as the analytical signal in automatic titrators.

Grans method (9,10) involves the use of the Nernst equation:

$$E = E^* + S \log C_i$$

where

S is electrode slope, E^* is $E' \pm (0.0591/n) \log i$, and

and E' is the constant incorporating the potential of the reference electrode and the standard potential of the half-cell containing the solution under investigation and the ion selective electrode. The rearrangement of this equation gives:

$$\log C_i = (E - E^*)/S$$

or

$$\begin{aligned} C_i &= \text{antilog}[(E - E^*)/S] \\ &= [\text{antilog}(-E^*/S)][\text{antilog}(E/S)] \end{aligned}$$

The first antilog term is a constant and therefore:

$$C_i = \text{const} \cdot [\text{antilog}(E/S)]$$

If the species i is disappearing during the course of the titration, then it will do it linearly. The antilog term reduces linearly, and a plot of antilog (E/S) against volume of reagent added should give a straight line whose intercept with the volume axis will be the equivalence point, as shown in Fig. 11.

Applications

Precipitation and complex-formation titrations

The indicator electrode for a precipitation titration is often the metal from which the reacting cation is derived. Membrane electrodes that are sensitive to one of the ions involved in the titration process may be used. For example, fluoride-sensitive membrane electrode is used in the determination of the fluoride content of toothpastes. Lanthanum(III) solution is used as a precipitant.

Silver nitrate is the most commonly used reagent for precipitation titration, including potentiometric determination of endpoint. Argentometric methods exist for the determination of halides, halogenoids, mercaptans, sulfides, phosphates, oxalates, and arsenates. A silver electrode serves as indicator for the potentiometric determination of these ions. If the concentration of reagent and analyte is 0.1 *M* or higher, then a calomel electrode can be used. In dilute solutions, the slight leakage of chloride ions from the salt bridge could be a source of significant error, but not in more concentrated solutions.

Mercury electrode can be used for the potentiometric determination of 29 divalent, trivalent, and tetravalent cations with EDTA (11, 12).

Neutralization titrations

Potentiometric acid–base titrations are particularly useful for the analysis of mixtures of acids or polyprotic acids (or bases) because often, discrimination between the endpoints can be made. An approximate numerical value for the dissociation constant of a weak acid or base can be estimated from potentiometric titration curves. In theory, this quantity can be obtained from any point along the curve, but it is most easily derived from the pH at the point of half-neutralization.

In the case of weak acid HA, it can be assumed that at the midpoint, $[HA] = [A^-]$, and thus:

$$K_a = [H^+][A^-]/[HA] = [H^+]$$

which gives

$$pK_a = pH$$

It must be noted that this constant is not correct because activities should be used in calculations:

$$K_a = [A^-]f_A/[HA]f_{HA}$$

and because

$$[HA] \text{ and } [A^-] \text{ are equal } K_a = f_A/f_{HA}$$

Oxidation–reduction titrations

In oxidation–reduction titrations, an electrode potential related to the concentration ratio between the oxidized and reduced forms of either of the reactants is determined as a function of the titrant volume. The indicator electrode must be responsive to at least one of the couples involved in the reaction. Indicator electrodes for oxidation–reduction titrations are generally constructed from platinum, gold, mercury, or palladium. The metal chosen must be unreactive with respect to the components of the reaction. The indicator metal is merely a medium for electron transfer.

Automatic Titrators

An entire titration can be performed automatically by titrators equipped with microcomputers and analog-to-digital converters and using dedicated software (13). The most widely used apparatus for automatic reagent addition consists of a calibrated syringe that is activated by a motor-driven micrometer screw. The volume is determined from the number of turns the screw makes during the titration.

Another method uses a preset equivalence point potential applied across the electrodes by means of a calibrated potentiometer. A difference between this potential and that of the electrodes causes an “error” signal, which is amplified. This causes the electronic switch to close, permitting a flow of electricity through the solenoid-operated valve of the burette. As the signal approaches zero, the flow of titrant ceases as the current to the solenoid is switched off.

Second-derivative titrators have the advantage that no preknowledge of the equivalence point potential is required. The signal processor calculates the second derivative of the electrode potential of the indicator electrode. Change in the sign of the second derivative causes a switching device to turn off the flow of the titrant.

A fully automated unit accepts a series of samples placed on a turntable. After each titration, the turntable rotates, indexes the next sample beneath the electrode assembly, and starts the titration.

CONDUCTOMETRIC TITRATIONS

Theory

Conduction of an electric current through an electrolyte solution involves migration of positively charged species toward the cathode and negatively charged species toward the anode. The conductance of a solution is

a measure of the current flow that results with application of a given electrical force. It is directly dependent on the number of charged species the solution contains (14). The conductance L of a solution is also the reciprocal of the electrical resistance and has the units of ohm:

$$L = 1/R$$

where R is the resistance in ohms.

The conductance is directly proportional to the length (l) of a uniform conductor. Thus:

$$L = kA/l$$

where k is a proportionality constant called the specific conductance, and A is the surface area.

The equivalent conductance, Λ , is defined as the conductance of a 1-g equivalent of solute contained between electrodes spaced 1 cm apart. It is equal to L when 1-g equivalent of solute is contained between electrodes spaced 1 cm apart. The volume V of solution (cm^3) that will contain 1 gram equivalent solute is given by:

$$V = 1000/C$$

where C is the concentration in equivalents per liter.

Volume can also be expressed in terms of the dimensions of the cell:

$$V = lA$$

when l is 1 cm

$$V = A = 1000/C$$

when $L = kA/l$,

$$\text{when } L = kA/l$$

$$\text{and } \Lambda = L, \text{ then } \Lambda = 1000k/C$$

A conductometric titration involves measurement of the conductance of the sample after successive additions of reagent. The endpoint is determined from a plot of either the conductance or the specific conductance as a function of the volume of added titrant. Throughout a titration, the volume of the solution is always increasing. Unless the conductance is corrected for this effect, nonlinear titration curves result. The titrant should be at least 10 times as concentrated as the solution being titrated to keep the volume change small. Some temperature control is ordinarily required during a conductometric titration because the temperature coefficient for conductance measurements is approximately 2% per °C.

Titration Curves

Titration curves for conductometric titrations take a variety of shapes, depending on the chemical system under investigation. In general, they are characterized by straight line portions with dissimilar slopes on either side of the equivalence point, as shown previously in Fig. 3. To establish a conductometric endpoint, after correcting for volume changes, the conductance data are plotted as a function of titrant volume. The two linear portions are then extrapolated, and the point of intersection is taken as the equivalence point. Frequently, reactions fail to proceed to absolute completion, and the conductometric titration curves invariably show departures from strict linearity in the region of the equivalence point.

An advantage of the conductometric titration is that it can be used for titrations based on relatively unfavorable equilibria.

Applications

Acid–base titrations

Neutralization titrations are particularly well-adapted to the conductometric titration because of the very high conductance of the hydronium and hydroxide ions compared with the conductance of the reaction products. In neutralization of strong acids, hydronium ions are being replaced by an equivalent number of less mobile sodium ions, and the conductance decreases as a result of this substitution. At the equivalence point, the concentration of hydronium and hydroxide ions are at a minimum, and the solution exhibits its lowest conductance. After the endpoint, a reversal of slope occurs as the sodium ion and the hydroxide ion concentration from the excess base increase. There is an excellent linearity between conductance and the volume base added, except at very near equivalence point region. Very dilute solutions can be analyzed accurately.

In conductometric titrations, a change in conductance is caused after the endpoint owing to the increase in concentration of the mobile hydroxide ion. Very weak acids (such as boric acid) and moderately weak acids (such as acetic acid) can be titrated using conductometric titration.

If the titrant is a weak electrolyte (such as ammonia), the curve is essentially horizontal past the equivalence point, which causes less uncertainty to the extrapolation of a curve. In titration of a weak base, such as acetate ion, with a strong acid, a salt and undissociated acetic acid are formed. After the endpoint is passed, a sharp rise in conductance attends the addition of excess hydronium

Fig. 12 Titration of chloride ion with silver nitrate.

ions. Salts whose acidic or basic character is too weak to give satisfactory endpoints with indicator are conveniently titrated with the conductometric method. The conductometric titration of a mixture of two acids that differ in degree of dissociation is frequently more accurate than a potentiometric titration.

Precipitation and complex-formation titrations

Figure 12 illustrates the titration of sodium chloride with silver nitrate. After all chloride is precipitated, the addition of excess silver nitrate causes a rapid increase in conductivity. The slope of the initial portion of the curve may be either downward or upward, depending on the relative conductance of the ion being determined and the ion of like charge in the reagent that replaces it. Slow reactions and coprecipitation are sources of difficulty with precipitation and complex-formation titrations.

COULOMETRIC TITRATIONS

Theory

A coulometric titration uses an electrolytically generated titrant for reaction with the analyte. In some analyses, the active electrode process involves only generation of the reagent. In other titrations, the analyte may also be directly involved at the generator electrode (15). The current in a coulometric titration is carefully maintained at a constant and accurately known level. The product of this current and

the time required to reach the equivalence point for the reaction yield the number of coulombs and thus the number of equivalents involved in the electrolysis. The coulomb (C) is the quantity of electricity that is transported in 1 by a constant current of 1 ampere. The Faraday constant (F) is the quantity of electricity that produces one equivalent of chemical change at an electrode (16).

The so-called primary titration technique is attempted only with electrodes of silver metal, silver–silver halide, or mercury amalgams, which are the source of the electrogenerated species. The substance to be determined reacts directly at the electrode or with a reactant electrogenerated from the working electrode. This class of titrations is limited generally to nondiffusible reactants such as mercury amalgams, silver ions generated by anodization of silver metal, and halides liberated by reduction of the appropriate silver–silver halide electrode.

In secondary coulometric titrations, an oxidation–reduction buffer serves as the titrant precursor. An active intermediate from the titrant precursor must first be generated with 100% efficiency by the electrode process. The intermediate must react rapidly and completely with the substance being analyzed.

The endpoint may be detected by addition of colored indicators, provided the indicator itself is not electroactive. Potentiometric and spectrophotometric indication is used in acid–base and oxidation–reduction titrations. Amperometric procedures are applicable to oxidation–reduction and ion-combination reactions especially for dilute solutions.

The most obvious advantage of coulometric titration is the elimination of problems associated with the preparation, standardization, and storage of standard solutions. This is particularly important for labile reagent substance such as chlorine or bromine. Another advantage is the requirement of a small quantity of reagent. Instrumentation is simple; a single constant-current source can be used to generate precipitation, oxidation–reduction, or neutralization reagents. Furthermore, coulometric titration is easily automated.

Typical sources of error in coulometric titrations are variation in the current during electrolysis and errors in measurement of current and time. Departure of the process from 100% current efficiency is the primary error source. In some cases, the equivalence point is not the endpoint of the titration.

Applications

Neutralization titrations

Both weak and strong acids can be titrated with a high degree of accuracy using electrogenerated hydroxide ions.

Table 4 Coulorimetric titrations of oxidation–reduction reactions

Reagent	Substance determined
Br ₂	As ³⁺ , Sb ³⁺ , U ⁵⁺ , NH ₃ , N ₂ H ₄ , NH ₂ OH, phenol, aniline
Cl ₂	As ³⁺ , I [−]
I ₂	As ³⁺ , Sb ³⁺ , S ₂ O ₃ ^{2−} , H ₂ S
Ce ⁴⁺	Fe ²⁺ , Ti ³⁺ , U ⁴⁺ , As ³⁺ , I [−] , Fe(CN) ₆ ^{3−}
Fe ²⁺	Cr ⁶⁺ , Mn ⁷⁺ , V ³⁺ , Ce ⁴⁺
Ti ³⁺	Fe ³⁺ , V ⁵⁺ , Ce ⁴⁺ , U ⁶⁺
C ₂ Cl ₃ [−]	V ⁵⁺ , Cr ⁶⁺ , IO ₃ [−]

In this application, the platinum anode must be isolated by some sort of diaphragm to eliminate potential interference from the hydrogen ions produced. Alternatively, chloride or bromide ions can be added to the solution, and a silver wire used as an anode. The reaction at this electrode is:

Thus, this anode product does not interfere with the neutralization reaction.

Strong and weak bases can be titrated with hydrogen ions generated at a platinum anode.

Here also the cathode must be isolated from the solution to prevent interference from the hydroxide ions produced at that electrode.

Precipitation and complex-formation titrations

Anodically generated silver ions can be used for precipitation titrations of various substances. A cell constructed from a piece of heavy silver wire can be used. Substances precipitated include Cl[−], Br[−], I[−], and mercaptans. Similar applications using mercury(I) ion formed at a mercury anode have been used for the determination of Cl[−], Br[−], and I[−].

The complexing ability of ethylenediaminetetra-acetic acid (EDTA, H₄Y) has been exploited in the coulometric titration of metal ions. The method depends on the reduction of the mercury(II) or cadmium chelate of EDTA and on the titration of the metal ion (for example, magnesium) to be determined by the anion of EDTA that is released.

Oxidation–reduction titrations

Applications of coulometric titrations involving oxidation–reduction reactions are shown in Table 4. Electrogenerated oxidizing agents such as bromine have proved to be useful, especially in organic analysis.

AMPEROMETRIC TITRATIONS

Theory

Polarographic methods can be used to estimate the equivalence point of a reaction, provided that at least one of the participants or products of the titration is oxidized or reduced at the microelectrode. When the potential applied across the two electrodes is maintained at some constant value, the current may be measured and plotted against the volume of the titrant, thus, the term amperometric titration. In the case of working electrode-reference electrode pair, the potential of the indicator electrode is maintained at a constant value with respect to a reference electrode, measuring a limiting current, which is proportional to the concentration of one or more of the reactants or products of the titration.

Amperometric titration is easily automated. The titrator can be programmed to shut off when a specified current level is reached. Titrant is run into a blank solution until a specified current is reached, the sample is added, and the titrant is again added until the specified current level is reached.

A correction for dilution is necessary to attain a linear relationship between current and volume of titrant. By working with a reagent that is 10-fold more concentrated than the solution being titrated, this correction becomes negligible. Amperometric and conductometric titrations are similar in the respect that the data for each are collected well away from the equivalence point. Therefore, reactions that are relatively incomplete can be used.

Titration Curves

Typical forms of amperometric titration curves are shown in Fig. 13. A titration in which the substance being analyzed reacts (is reduced) at the electrode while the reagent does not is shown in Fig. 13a. A sufficiently high potential is applied to give a diffusion current for

Fig. 13 Amperometric titration curves: (a) analyte is reduced, reagent is not; (b) reagent is reduced, analyte is not; (c) both reagent and analyte are reduced.

the substance, and a linear decrease in current is observed as substance ions are removed from the solution by precipitation. The curvature near the equivalence point reflects the incompleteness of the analytical reaction in this region. The endpoint is obtained by extrapolation of the linear portions. Nearly a mirror image curve is obtained for a titration in which the reagent reacts (is reduced) at the microelectrode, and the substance being analyzed does not (Fig. 13b). The third common curvature for amperometric titrations is obtained when both reagent and substance analyzed react (are reduced) at the electrode (Fig. 13c).

Amperometric Titrations with Two Polarized Microelectrodes

A modification of amperometric method involves the use of two stationary microelectrodes immersed in a well-stirred solution of a sample (17). A small potential is applied between these electrodes, and such current that flows is followed as a function of the volume of reagent added.

Oxidation–reduction titrations

Twin polarized platinum microelectrodes are conveniently used for endpoint detection for oxidation–reduction titrations. Consider a titration curve for oxidation–reduction titration where both reactants behave reversibly at the electrodes. An example of this kind of titration is titration of iron(II) with cerium(IV) (Fig. 14a). At the starting point of the titration, no current is observed because no suitable cathode reactant is available. With addition of cerium(IV), a mixture of iron(II) and iron(III) is produced, which permits the passage of current. Beyond the midpoint in the titration, iron(III) becomes in excess, and the current is then regulated by decreasing iron(II) concentration. At the equivalence point, the current approaches zero because iron(III) are present, and the applied potential is not great enough to cause these to react at the electrode. Beyond the equivalence point, the current

rises again because both cerium(III) and cerium(IV) are present to react at the electrodes.

In cases where only reagent behaves reversibly, a different form for titration curve is obtained. Although the reagent added can serve as an anode reactant, no cathode reactant is available because of the slow rate at which the substance analyzed is reduced at a platinum surface. Therefore, no current is observed. Beyond the equivalence point, depolarization of the cell can occur, and the current is dependent on the concentration of the reagent (Fig. 14b). In cases where only the species titrated behave reversibly, before equivalence point, a current is observed that depends on the concentration of the species present in lesser amount. At equivalence point, a zero current is reached, and beyond the equivalence point, no current is observed because the reagent does not behave reversibly at the electrodes (Fig. 14c).

Precipitation titrations

Twin silver microelectrodes permit observation of the endpoint for various titrations using silver nitrate as precipitation reagent (Table 5). Short of the equivalence point, essentially no current exists when a small potential is applied between two such electrodes during a titration of substance analyzed with silver ions because no easily reduced species is present in the solution. After equivalence, the cathode becomes depolarized owing to the presence of a significant amount of silver ions that can react to give silver. Current is permitted as a result of this half-reaction and the corresponding oxidation of silver at the anode. The magnitude of the current is directly proportional to the concentration of the excess reagent.

PHOTOMETRIC TITRATIONS

The change in absorbance of a solution may be used to follow the change in concentration of a radiation-absorbing

Fig. 14 Amperometric titration curves with twin polarized electrodes: (a) both reactants behave reversibly at the electrode; (b) only reagent behaves reversibly; (c) only analyte titrated behaves reversibly.

Table 5 Applications of amperometric titrations with precipitation products

Reagent	Substance determined
AgNO ₃	Cl [−] , Br [−] , I [−] , CN [−] , RSH
Cupferron	Cu ²⁺ , Fe ³⁺
Dimethylglyoxime	Ni ²⁺
Pb(NO ₃) ₂	SO ₄ ²⁺ , MoO ₄ ²⁺ , F [−] , Cl [−]
8-Hydroxyquinoline	Mg ²⁺ , Cu ²⁺ , Zn ²⁺ , Cd ²⁺ , Al ³⁺ , Bi ³⁺ , Fe ³⁺
K ₂ CrO ₄	Pb ²⁺ , Ba ²⁺

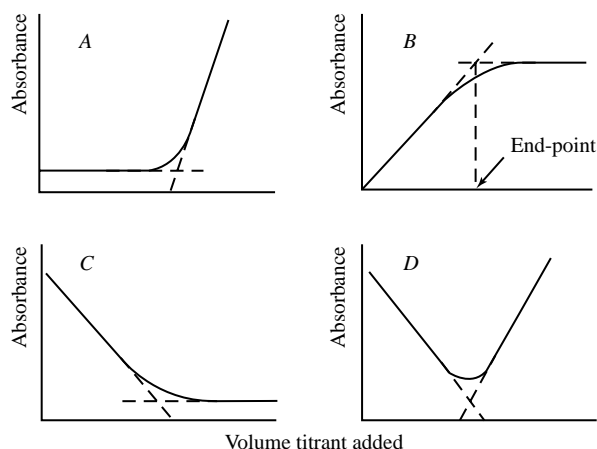

Fig. 15 Different shapes of photometric titration curves.

constituent during a titration (18). The absorbance is directly proportional to the concentration of the absorbing constituents. A plot of absorbance versus titrant consists, if the reaction is complete, of two straight lines that intersect at the endpoint. If the reaction is appreciably incomplete, extrapolation of the two linear segments of the titration curve establishes the intersection and endpoint volume.

Photometric titrations have several advantages over a direct photometric determination. The presence of other absorbing species at the analytical wavelength does not necessarily cause interference because only the change in absorbance is significant. However, if the absorbance of nontitratable components is intense, the absorbance readings are shifted to the undesirable upper end of the absorbance scale. Ideally, only a single absorber is present among the reactant, titrant, and products.

The analytical wavelength is selected to avoid the interference caused by other absorbing substances. Also, there is a need for a molar absorptivity that causes the change in absorbance during the titration to fall within a convenient range. Often, the chosen wavelength lies well apart from an absorption maximum.

Titration Curves

Volume change, caused by addition of titrant, is seldom negligible, and straight lines for titration curve are obtained only if there is correction for dilution.

If correction is not made, the lines are curved downward toward the volume axis, and erroneous intersections are obtained. Use of a microsyringe and a relatively concentrated titrant is desirable.

Possible shapes of photometric titration curves are shown in Fig. 15. Curve A is typical of the titration where

the titrant alone absorbs and where the absorbance readings are taken at the wavelength of the titrant. Curve B is characteristic of systems where the product of the reaction absorbs, and curve C is typical for reactions where the analyte is converted to a nonabsorbing product. When a colored analyte is converted to a colorless product by a colored titrant, curves similar to D are obtained.

Applications

Areas of particular applicability are for solutions so dilute that the indicator blank is excessive or when the color change is not sharp perhaps because titration reactions that are incomplete in the vicinity of the equivalence point or when extraneous colored materials are present in the sample. Titrations in solutions of high or low ionic strength and even in nonaqueous solution are easily performed. Sensitivity of the measurement can be changed easily by simply changing the wavelength or the length of the cell path, a feature that also makes photometric titration attractive. Indicators can be used in titrations where self-indicating systems are lacking.

TONICITY

Jaymin C. Shah

Pfizer Inc., Groton, Connecticut, U.S.A.

INTRODUCTION

Parenteral formulations, both large and small volume, have been discussed in depth in Volume 11 of the *Encyclopedia of Pharmaceutical Technology* (V 11, pp. 201–217, 217–237). However, no discussion of parenteral formulations is complete without an adequate description of tonicity. Tonicity is an important factor in the formulation of products intended for application to sensitive mucous membranes of organs such as eye, ear, and nose. In this article, an attempt is made to first introduce tonicity with respect to its physiological significance, followed by a discussion of the physicochemical basis for tonicity and colligative properties. Then, a brief review of methods of measuring and/or calculating tonicity is given, followed by the established methods of adjusting tonicity and the examples illustrating each of the methods. Tables listing the established values necessary to do the calculations are provided at the end of the article. Excellent comprehensive reviews dealing with various aspects of tonicity are available in the literature in the form of chapters in various textbooks for pharmacy students (Remington's *Pharmaceutical Sciences*, *Physical Pharmacy* by Martin, etc.). A list of such reading material is provided at the end of the article in the Bibliography.

Dosage forms are drug-delivery systems designed to deliver drug to the systemic circulation or to a localized region of the human body. These dosage forms should ideally be free of any undesired adverse effects from the drug and from the formulation components. Reasonable risks associated with the drug substance are sometimes tolerated with an objective of realizing significant therapeutic advantages, as in the case of cancer chemotherapeutic agents. However, any untoward side effect, even as minor as irritation, resulting from an excipient or the finished dosage form cannot be accepted and should not be tolerated. This concern is particularly important to parenteral formulations that breach the normal defensive barriers of the human body to deliver the drug. Therefore, any formulation that comes in contact with sensitive mucous membranes of organs such as the eye should not result in tissue irritation and pain attributable to the formulation itself. One of the

physicochemical means by which a formulation may result in pain and tissue irritation is caused by the nonphysiological concentration of dissolved solutes coming in contact with sensitive tissues. Tonicity is a formulation property that has a direct influence on the ability of the formulation to result in tissue irritation, as described by the following example.

If a small quantity of blood defibrinated to prevent clotting is mixed with a solution containing 0.9% w/v of NaCl, the red blood cells remain intact and retain their normal size and shape. The NaCl solution is considered to be isotonic and has essentially the same salt concentration as does the red blood cell. In contrast, if the blood is mixed with 1.8% w/v NaCl solution, erythrocytes shrink and become wrinkled or crenated as if the cell content has been sucked out. The salt solution that causes this is considered hypertonic with respect to the red blood cell contents. It is because the red blood cell contains a lower salt concentration than the surrounding 1.8% w/v salt solution and as if the water from the erythrocytes passes through the cell membrane to dilute the surrounding salt solution to equalize the two salt concentrations across the membrane. The opposite phenomenon occurs if blood is mixed with 0.45% w/v NaCl solution. Water from the surrounding salt solution enters the erythrocytes, causing them to swell and finally burst, with the liberation of hemoglobin. The 0.45% w/v salt solution is considered hypotonic, and the phenomenon is known as hemolysis. The physiological significance of hemolysis was reconfirmed recently by the report of 10 episodes of hemolysis among patients who received hypotonic 25% human albumin because of dilution with sterile water instead of isotonic sodium chloride (1). Two of these 10 recipients exhibited significant hemolysis and adverse pathological conditions, with one resulting in death (1). Also, it has been observed that hypertonic and hypotonic salt solutions tend to irritate sensitive mucous membranes of the eye, the nose, and the muscle when applied. However, an isotonic solution causes no tissue irritation when it comes in contact with the tissue. The crenation and the hemolysis of red blood cells in hypertonic and hypotonic salt solution, respectively, can be explained by the movement of water across the cell membrane. A membrane is defined as semipermeable if it allows only the movement of solvent molecules

across it. The process of diffusion of a solvent through a semipermeable membrane from a less-concentrated solution to a more-concentrated solution is known as osmosis. The pressure that must be applied to the concentrated solution side of the membrane to prevent the flow of pure solvent across the membrane from the diluted solution is known as the osmotic pressure. In crenation, water diffuses from the inside of the erythrocyte across the membrane into the exterior hypertonic salt solution. Hemolysis occurs when water diffuses from the exterior hypotonic solution into the erythrocyte, causing it to swell and burst. An isotonic solution is an aqueous solution that generates the same "tone," or osmotic pressure, as the body fluids across biological membranes and thus prevents water flow in either direction and hence is nonirritating when injected, instilled, perfused, or brought into contact with sensitive mucous membranes. When a solution is hypertonic or hypotonic, osmotic water flow occurs and tone of the membrane is affected. Thus, formulators need to adjust the tone, or tonicity, of the solution to be isotonic with physiological fluids. To be able to adjust the tonicity of a formulation to the isotonic state, one has to understand the principles behind the generation of the osmotic pressure resulting from the dissolved solutes and how it can be altered to that of the physiological fluids.

Osmotic pressure is a colligative property unlike the additive and constitutive properties of solution. Simply stated, the colligative properties of a solution are dependent solely on the number of nonsolvent (solute) particles (molecule/ions) dissolved or in a true solution form in a given solvent and are independent of the specific physicochemical characteristics of the nonsolvent dissolved substance(s). For example, two nonelectrolyte solutes A and B when prepared as 0.1M solutions will exhibit the same osmotic pressure irrespective of the chemical nature of A and B. Experimentally, it has been found over the years that the colligative properties are indeed independent of the solute nature and dependent solely on the number of independent particles in dilute solutions for a wide variety of solutes, provided the number of particles is properly assessed. An implicit assumption in the statement above is that the solute is nonvolatile relative to the solvent and the reasoning will be clear from the discussion that follows. The colligative properties of solution are vapor pressure lowering, boiling-point elevation, freezing-point depression, and osmotic pressure. These four properties are effects of solute on the solvent, in that it reduces the escaping tendency of the solvent, and all of them can be related to vapor pressure lowering of the solution. Osmotic pressure is of primary importance from the formulation standpoint; however, it is

cumbersome to measure, and therefore other colligative properties are determined because they are all interrelated. The theory of the colligative properties has been well-established and reviewed in depth in the various textbooks and in the pharmaceutical literature (see the Bibliography). And because the focus of this *Encyclopedia* is on pharmaceutical technology rather than on the theoretical foundation, we briefly overview the theory of colligative properties as needed to understand the concepts used in methods to adjust tonicity of parenteral and ophthalmic formulations.

RAOULT'S AND HENRY'S LAWS AS BASIS FOR COLLIGATIVE PROPERTIES

Raoult's law states that in an ideal solution, the partial vapor pressure of each volatile constituent is equal to the vapor pressure of the pure component multiplied by its mole fraction in the solution. Thus, for two constituents A and B in solution:

$$P_B = P_B^o X_B \quad (1)$$

$$P_A = P_A^o X_A \quad (2)$$

where P_A and P_B are the partial vapor pressures of constituents A and B over their solution when the fractional molar concentrations are X_A and X_B , and the vapor pressure of the pure constituents are P_A^o and P_B^o . Therefore, it can be inferred that the vapor pressure of B above the solution by dilution with A is reduced relative to its vapor pressure in pure state and vice versa for A. This diminishes the escaping tendencies of each component, leading to a reduction in the rate of escape of the molecules of A and B from the surface of the solution. This law is valid only in ideal solutions in which there are no intermolecular interactions between components A and B (adhesive interactions) or in which interactions between the two components A and B are identical to the interactions of the pure components A and pure B (cohesive interactions between A and A and between B and B). In essence, the molecule of each component sees an environment identical to its molecular environment in the pure state. This refers to an infinitely dilute solution in which a component's thermodynamic activity is equal to its concentration. However, in the real solutions, the assumption noted above may not apply, and negative deviation from Raoult's law may occur when adhesive attractions between A and B are greater than cohesive attraction within pure A or pure B molecules; i.e., the vapor pressure of the solution or the partial vapor pressure

of each component is lower than that expected based on Raoult's law applied to ideal solution. Similarly, positive deviations from Raoult's law can occur when interactions between A and B are less than the cohesive interactions of pure A or pure B, resulting in vapor pressures higher than that expected based on Raoult's law applied to ideal solution. In general, Raoult's law states that when a component A is diluted with another component B, the partial vapor pressure of A is reduced; in essence, a dilution effect.

Raoult's law does not apply over the entire concentration range in a nonideal, real solution. However, when one component is in a large enough excess to be considered a solvent, Raoult's law may be expressed as:

$$P_{\text{solvent}} = P_{\text{solvent}}^{\circ} X_{\text{solvent}} \quad (3)$$

in such a dilute solution and is valid only for the solvent component of a nonideal solution that is sufficiently dilute for the other component, i.e., the solute in a dilute nonideal solution. In such a dilute solution, the solute molecule is completely surrounded by solvent molecules such that the solute molecule can interact only with the solvent molecules because there are very few solute molecules. Further dilution beyond this point does not alter a solute molecule's environment and, even if the solute molecule interacts with the solvent molecule, the solute's partial vapor pressure or the thermodynamic activity becomes proportional to its fractional molar composition as:

$$P_{\text{solute}} = K_{\text{solute}} X_{\text{solute}} \quad (4)$$

Eq. 4 is known as Henry's law, and K_{solute} is the Henry's law constant, which is less than $P_{\text{solute}}^{\circ}$. Therefore, Henry's law applies to the solute in dilute solutions, and Raoult's law applies to solvent in dilute nonideal solutions. Note the similarities between Eqs. 1 and 2 and between Eqs. 3 and 4 for the nonideal dilute solution case. When the solution is ideal, Henry's law becomes identical to Raoult's law, and K_{solute} becomes identical to $P_{\text{solute}}^{\circ}$. When the partial pressures of the solute and the solvent are directly proportional to their mole fractions over the entire range, the solution is ideal. In a nonideal solution, Raoult's law will apply to the solvent over the entire concentration range, whereas Henry's law will apply to the solute in a limited concentration range in which it is in a sufficiently diluted form.

When a nonvolatile solute is dissolved in a solvent, the partial vapor pressure of the solvent above the solution is equal to the vapor pressure of the solution. And because

the mole fraction of the solvent is $X_{\text{solvent}} = 1 - X_{\text{solute}}$, Eq. 3 can be rewritten as:

$$P_{\text{solution}} - P_{\text{solvent}} = P_{\text{solvent}}^{\circ} (1 - X_{\text{solute}}) \quad (5)$$

for the dilute solution of a nonvolatile solute of mole fraction X_{solute} . Therefore, the important conclusion from Raoult's and Henry's laws is that the thermodynamic activity of a solvent as measured by its vapor pressure is proportional solely on the mole fractional composition of the solute, irrespective of the physical and chemical nature of the dissolved species. The vapor pressure of the solvent above the solution thus depends solely on the number of particles (molecules/ions) of the dissolved solute and not on the weight concentration of the solute in solution. Therefore, the vapor pressure of a solvent above a dilute solution that obeys Henry's law is a colligative property of the solution. Henry's law has been found to be applicable to nonelectrolyte-type solute mole fractional concentrations of 0.1; however, the range is much smaller for electrolyte type solutes owing to the long-range nature of interionic interactions as noted above. Its impact is evaluated later below.

COLLIGATIVE PROPERTIES

Raoult's law forms the basis for the colligative properties, and Henry's law sets the limits of the applicability of Raoult's law to colligative properties of a solution as increasing amounts of solute are added to solution. As noted above, colligative properties are a consequence of the number of dissolved particles in solution and are all related to the escaping tendency of the solvent from solution.

The four colligative properties that are of importance are: 1) the vapor pressure lowering, 2) the elevation of boiling point, 3) the freezing-point depression, and 4) the osmotic pressure. An attempt is made below to describe qualitatively and quantitatively each colligative property of solutions, with an emphasis on their interrelationship and their application later in measurement and adjustment of the tonicity of solutions, with particular reference to parenteral formulations. Although theoretical derivations based on thermodynamics can be used to show how each of the colligative properties of solution arises and relate to each other, textbooks on physical chemistry for theoretical derivations are recommended.

Lowering of Vapor Pressure

The addition of a nonvolatile solute to a solvent leads to a reduction in the vapor pressure of the solvent because of a

reduction in thermodynamic activity of the solvent. Also, because the solute is nonvolatile, the vapor pressure of the solvent is the vapor pressure of the solution, as seen from Eq. 5. Qualitatively, one can imagine that fewer numbers of solvent molecules are escaping per unit surface area of the solution than from the pure solvent because fewer solvent molecules are present per unit surface area of the solution owing to displacement by solute molecules. However, these solute molecules will not affect the condensation of solvent molecules with insufficient kinetic energy present in the vapor phase. The result is a net reduction in escaping tendency of solvent molecules on the surface, causing a lowering of vapor pressure and, consequently, the rate of vaporization. The resulting vapor pressure lowering ($P_{\text{solvent}}^{\circ} - P_{\text{solution}}$) and the relative vapor pressure lowering as a function of mole fractional concentration of solute can be obtained by rearranging Eq. 5 to Eq. 6:

$$\frac{P_{\text{solvent}}^{\circ} - P_{\text{solution}}}{P_{\text{solvent}}^{\circ}} = \frac{\Delta P}{P_{\text{solvent}}^{\circ}} = X_{\text{solute}} \quad (6)$$

The left term is the relative vapor pressure lowering, which is solely dependent on the mole fraction concentration of a single solute or the sum of mole fraction of each solute dissolved in the solution. Thus, the relative vapor pressure lowering is a direct measure of the total number of dissolved solute particles, irrespective of their physicochemical nature. The mole fractions can be converted into molality (m moles of solute per 1000 g of solvent) to result in the following equation for water as the solvent:

$$\frac{\Delta P}{P_{\text{solvent}}^{\circ}} = X_{\text{solute}} \cong \frac{m M_{\text{solvent}}}{1000} \quad (7)$$

$\cong 0.018 m$ for Aq. solutions

where m is the concentration of solute expressed in molality, and M_{solvent} is the molecular weight of the solvent in grams. For water, $M = 18$, and because the density of water is close to 1, for dilute aqueous solutions, the molality and molarity (moles/liter) can be used interchangeably, and Eq. 7 can be used to calculate the relative vapor pressure lowering from the molar concentration of the nonelectrolyte solute.

Elevation of the Boiling Point

The boiling point of a liquid is the temperature at which the vapor pressure of the liquid becomes equal to the external pressure acting on the liquid, which is 760 mm Hg at one atmospheric pressure. Therefore, the boiling point of a solution of nonvolatile solute will be higher than that of the pure solvent owing to the solute reducing the vapor

pressure of the solvent above the solution according to Raoult's law. The solution has to be heated to a higher temperature to achieve the same vapor pressure to result in boiling of the solvent. The elevation of the boiling point ($T_{\text{solution}} - T_{\text{b}}^{\circ}$) is directly proportional to the relative vapor pressure lowering based on the Clausius–Clapeyron equation, resulting in an equation relating it to molality as follows:

$$(T_{\text{solution}} - T_{\text{b}}^{\circ}) = \delta T_{\text{b}} = \Delta T_{\text{b}} = K \Delta P = K_{\text{b}} m \quad (8)$$

where in K_{b} is called the molal elevation constant or the ebullioscopic constant, a characteristic constant for each solvent, and is the boiling point elevation of an ideal 1-molal solution of a nonvolatile solute. K_{b} can be obtained by measuring the $\delta T_{\text{b}}/m$ of several molal concentrations of solute in solutions and extrapolating the $\delta T_{\text{b}}/m$ versus molality curve to zero solute concentration. The value of K_{b} for water is $0.515^{\circ} \text{ kg/mole}$. By measuring the boiling point elevation of a solvent in a solution and knowing the K_{b} for that solvent, one can calculate the molal concentration of a solute in the solution. From Eq. 8, it is evident that the elevation of boiling point is a colligative property like vapor pressure lowering because it is strictly dependent on the molal concentration of the solute: the number of particles in solute and, thus, independent of the physicochemical nature of the solute.

Freezing-Point Depression

The freezing point of a liquid or the melting point of a solid phase of a pure compound is the temperature at which the solid and liquid phases are in equilibrium at a pressure of 1 atm. The freezing point of a pure compound is described by a unique point in the phase diagram of the compound, and, at that point, the solid and liquid phases are in equilibrium, and the vapor pressure of the liquid phase coincides with the vapor pressure of the pure solid phase. Because in a solution, the vapor pressure of the solvent is lowered relative to the pure solvent, no freezing (or crystallization) takes place at the equilibrium temperature of the liquid and solid phases of the pure solvent; i.e., the freezing point. The phase with the lower vapor pressure is the more stable phase thermodynamically. Therefore, cooling of the solution below the freezing point of the pure solvent results in a greater reduction in vapor pressure of the pure solid phase than the solution phase, and when the vapor pressure of the two phases eventually coincides, freezing (crystallization) of the pure liquid solvent occurs. The dissolved solute reduces the escaping tendency of the solvent molecules to crystallize, and thus the temperature must be reduced to reestablish

equilibrium between the solid and liquid phases and hence the depression of freezing point. It must be noted that the dissolved solute only affects the freezing of the liquid phase and does not alter the tendency of the molecules to leave the solid phase, although both processes are occurring in equilibrium at the freezing point. Also, the solvent should form a pure solid; if the solute cocrystallizes with the solvent, the phenomenon is complex and cannot be described as a colligative property. The more concentrated the solution, the greater the freezing-point depression, and using thermodynamic principles, Raoult's law, and Clausius–Clapeyron equation, the freezing-point depression can be related to solute concentration expressed in molality as follows:

$$(T_{\text{solution}} - T_f^o) = \delta T_f = \Delta T_f = K \Delta P = K_f m \quad (9)$$

where in K_f is called the molal depression constant or the cryoscopic constant, a characteristic constant for each solvent dependent on the physicochemical nature of the solvent, and is the freezing-point depression of an ideal 1-molal solution of a nonvolatile solute. K_f can be obtained experimentally by measuring the $\delta T_f/m$ of several molal concentrations of solute in solutions and extrapolating the $\delta T_f/m$ versus molality curve to zero solute concentration. The value of K_f for water is $1.86^\circ \text{ kg/mole}$. By measuring the freezing-point depression of a solvent in a solution and knowing the K_f for that solvent, one can calculate the molal concentration of a solute in the solution. Freezing-point depression is a colligative property as seen from Eq. 9, because it is proportional to molal concentration of solute; the number of particles in solution, and not on the physicochemical characteristics of the solute.

Osmotic Pressure

As described in the Introduction, the process of diffusion of a solvent through a semipermeable membrane from a less-concentrated solution into a more-concentrated solution is osmosis. This results in the development of a hydrostatic pressure head on the more-concentrated solution side of the membrane. Alternatively, pressure may be applied to the more-concentrated solution side of the semipermeable membrane to prevent the diffusion of solvent. This applied pressure on the concentrated solution is identical to the hydrostatic pressure head that may develop owing to osmosis. It is known as the osmotic pressure and is directly proportional to the solute concentration in an ideal solution. A semipermeable membrane is one that allows the movement of only solvent molecules, and if the membrane is not semipermeable,

osmosis may not be observed because the solute will diffuse quickly through the membrane to equalize the concentration on two sides of the membrane.

Osmosis tends to equalize the escaping tendencies of the solvent on both sides of the semipermeable membrane. Escaping tendency can be measured in terms of partial vapor pressure of solvent above the solution. Alternatively, one can see that at the beginning, the solution and pure solvents have different thermodynamic activities for the solvent because they have different vapor pressures. For the solution and pure solvent on two sides of the semipermeable membrane to be in equilibrium, they should have identical escaping tendency or identical vapor pressure and, thus identical thermodynamic activity. The equilibrium is therefore established by the generation of the osmotic pressure that compensates for the difference in solvent concentration on the two sides of the membrane, which is responsible for the different vapor pressures, escaping tendencies, and thermodynamic activity. Therefore, osmosis is a process to reach equilibrium state whereby solvent spontaneously flows from the high-free-energy (low-vapor-pressure) side of the membrane to the low-free-energy (high-vapor-pressure) side of the membrane, until the solvent's free energies on both sides of the membrane are equal and identical. Obviously, the solute will not be able to attain equilibrium because it cannot diffuse through the semipermeable membrane. Because osmotic pressure is attributable to the difference in vapor pressure of the solvent above solution, it is also a colligative property as explained below.

Using thermodynamics and considering free energy of the solvent as a function of vapor pressure, the osmotic pressure (π) that develops when a solution is separated from pure solvent by semipermeable membrane can be related to vapor pressures as shown below:

$$\Pi = \frac{RT}{V_{\text{solvent}}^M} \ln \frac{P_{\text{solvent}}^o}{P_{\text{solution}}} \quad (10)$$

where in R is the gas constant, T is temperature, V_{solvent}^M is the partial molar volume, (the volume occupied by 1 mole of solvent), and π is the developed osmotic pressure when a solution with vapor pressure P_{solution} is separated from a solvent with vapor pressure P_{solvent}^o by a semipermeable membrane. Applying Raoult's law and substituting mole fractions for the vapor pressures from Eq. 5 into Eq. 10 results in the following:

$$\Pi = \frac{-RT}{V_{\text{solvent}}^M} \ln(1 - X_{\text{solute}}) \cong \frac{RT}{V_{\text{solvent}}^M} X_{\text{solute}} \quad (11)$$

since $\ln(1 - X_{\text{solute}}) \cong -X_{\text{solute}}$

In a dilute solution, X_{solute} is approximately equal to the molar ratio $n_{\text{solute}}/n_{\text{solvent}}$, and Eq. 11 becomes:

$$\Pi = \frac{n_{\text{solute}}}{n_{\text{solvent}} V_{\text{solvent}}^M} RT = \frac{n_{\text{solute}}}{V_{\text{solution}}} RT = mRT \quad (12)$$

in which the number of moles of solvent multiplied by the partial molal volume is equal to the volume of the solvent in solution. In a dilute solution, the volume of solvent can be approximated to the volume of solution, which results in the above equation relating osmotic pressure to molar or molal concentration of a solute in solution. Eq. 12 is known as Morse's expression and demonstrates how osmotic pressure is a colligative property directly proportional only on the number of particles dissolved in the solvent irrespective of the nature of the solute. Van't Hoff had recognized early on that there is a direct proportionality among osmotic pressure and concentration of solute and temperature, and suggested a relationship that was similar to the equation for an ideal gas as follows:

$$\Pi V_{\text{solution}} = n_{\text{solute}} RT \quad (13)$$

Eq. 13 is analogous to the ideal gas equation, and van't Hoff concluded that osmotic pressure of a dilute solution was a pressure that the solute would exert if it behaved like a gas occupying that volume. Eq. 13 can also be expressed as:

$$\Pi = \frac{n_{\text{solute}}}{V_{\text{solution}}} RT = cRT \quad (14)$$

which shows that osmotic pressure is directly proportional to the concentration of solute expressed in molarity. This equation is similar to Morse's expression, Eq. 12; however, it has been shown theoretically and experimentally that more accurate results can be obtained when solute concentration is expressed in molality rather than in molarity. Although the resemblance of Eq. 13 to the ideal gas equation is striking, osmotic pressure is a result of differences in the escaping tendencies of the solvent on two sides of the membrane rather than of the behavior of a solute such as a gas.

From Eqs. 12–14, one finds that 1-molar solution of any solute will generate an incredibly high osmotic pressure of approximately 24 atm at room temperature, which has been verified experimentally. Although this estimate is based on the assumption that the solution is dilute and behaving ideally, at high concentrations of solute, the theory overestimates the experimental findings. The discussion above deals primarily with the thermodynamic basis for the generation of osmotic pressure; however, it does not address the issue of how fast the equilibrium is attained or how fast the osmotic pressure will be generated. The rate of generation of osmotic pressure is a kinetic process and depends to a great extent

on the characteristics of the semipermeable membrane. Red blood cell membrane or the mucous membrane in the eye are very thin and moist, and water can diffuse very rapidly through the membrane to generate the enormous osmotic pressure. However, the osmotic pressure may develop very slowly across synthetic and semisynthetic polymeric membranes, across which the diffusion is very slow.

COLLIGATIVE PROPERTIES OF ELECTROLYTES AS COMPARED WITH NONELECTROLYTE SOLUTES

The colligative properties, by definition, should be independent of the nature of the solute. Therefore, 0.1-molal solutions of sucrose and NaCl should exhibit similar colligative properties. It was observed by van't Hoff that colligative properties of dilute solutions of nonelectrolytes such as sucrose were expressed satisfactorily by the equations above. However, solutions of strong electrolytes such as salts gave osmotic pressure twice or three times as large as would be expected based on Eq. 14, depending on the electrolyte investigated. To account for this anomaly, van't Hoff proposed the following modification of Eq. 14 as shown below:

$$\Pi = i c RT \quad (15)$$

in which i can be considered to be a factor to account for the deviation of concentrated solutions of electrolytes and also nonelectrolytes from Raoult's law as applied to ideal solutions. After Arrhenius developed the theory of ionization or dissociation of salts into ions, van't Hoff and others recognized that the value of i approached or equaled the number of ions into which the electrolyte or the molecule dissociated as the solution was made more dilute. For example, a dilute 0.1- M solution of NaCl would be twice as active osmotically as a 0.1- M solution of sucrose, and i for NaCl was two. Similarly, 0.1- M solutions of CaCl_2 and MgCl_2 would generate three times the osmotic pressure of 0.1- M sucrose solution, and i for both is equal to three. Therefore, it was realized that i reflected the number of ions the electrolytes dissociated into and, thus, electrolytes at equimolar concentrations were more effective in generating osmotic pressure based on the number of ions they produced on dissociation. However, it was also observed that at moderate concentrations of electrolytes, osmotic pressures were less than that expected based on complete dissociation. In fact, this led the scientific community to suggest partial dissociation for even strong electrolytes and to use

colligative properties as a measure of degree of dissociation. However, we know now that strong electrolytes do dissociate completely even in concentrated solutions from other measurements such as conductivity techniques. The lower-than-expected values of osmotic pressure in moderate concentrations of electrolytes is attributable to the influence of long-range ionic interactions that come into play as the solution gets increasingly concentrated. The basic assumption in Raoult law was that there was no interaction between solute particles and, even if there was any, it should equal that between the solute and the solvent. However, the strong attractive forces between ions of opposite charges do predominate in increasingly concentrated solutions of electrolytes, and their thermodynamic activity is reduced relative to that in an infinitely dilute solution. Also, the effect of ionic strength of a solution has been shown to influence the activity of electrolytes, and thus, it is the interionic forces rather than the partial dissociation that seems to influence the colligative properties of electrolytes being lower than expected based on complete dissociation.

All the colligative properties of all solutes with the modification by the van't Hoff factor i can be expressed as:

$$\begin{aligned}\Delta P &= i P_{\text{solvent}}^{\circ} m; & \Pi &= i RT m; \\ \Delta T_f &= i K_f m; & \Delta T_b &= i K_b m\end{aligned}\quad (16)$$

where in i for nonelectrolyte should be 1 and for strong electrolytes equal the number of ions formed on dissociation. For example, i should be 2 for NaCl, 3 for CaCl_2 , and 4 for FeCl_3 . However, in reality, i is less than that calculated, based on the number of ions produced in concentrated solutions, but will approach the theoretical number in infinitely dilute ideal solutions. When the i value is calculated, for a number of solutions with increasing concentration of the solute and then extrapolated to zero concentration of the solute, one can obtain the theoretical i value. The van't Hoff factor has also been considered the ratio of any colligative property of a real solution to that of an ideal solution of a nonelectrolyte.

PHYSIOLOGICAL AND CLINICAL SIGNIFICANCE OF TONICITY

Osmotic pressure becomes important from a physiological standpoint because a majority of biological membranes are semipermeable, and body fluids such as blood and tears exhibit significant osmotic pressure owing to a

number of solutes dissolved in them. As noted above in the Introduction, if a small quantity of blood is mixed with a solution containing 0.9% w/v NaCl, the red blood cells remain intact and retain their normal size and shape. The NaCl solution is considered to be isotonic because it maintained the tone of the membrane of the red blood cell. In contrast, if the blood is mixed with the hypertonic 1.8% w/v NaCl solution, cells shrink and become wrinkled or crenated owing to its content being sucked out. It is because the red blood cell content exerts a lower osmotic pressure than does the surrounding hypertonic 1.8% w/v salt solution, and the water inside the cells diffuses through the cell membrane to dilute the surrounding salt solution to equalize the osmotic pressure across the membrane. The exact opposite phenomenon occurs if blood is mixed with hypotonic 0.45% w/v NaCl solution. Water from the surrounding salt solution enters the cells, causing them to swell and finally burst with the liberation of hemoglobin, and the phenomenon is known as hemolysis. The crenation and hemolysis of red blood cells in hypertonic and hypotonic salt solution, respectively, are explained by the movement of water across the cell membrane owing to the osmotic pressure differential. However, it is well-known that the different physiological membranes are different with respect to their permeability characteristics. The red blood cell membrane has been found to be permeable to small polar and semipolar solutes such as alcohol, boric acid, and urea, etc. Thus, the erythrocyte membrane is not truly semipermeable, and although 2% boric acid solution is iso-osmotic with erythrocyte cell contents, it causes hemolysis because boric acid moves freely across the membrane and its solution being hypotonic acts like pure water in its effect on erythrocytes. However, the same 2% boric acid solution is both iso-osmotic and isotonic with eye secretions and causes no irritation when instilled in the eye because the mucous membrane of the eye is a true semipermeable membrane. To resolve the confusion created by different permeability characteristics of biological membranes, the word isotonicity was created. The word isotonic refers to solutions that are iso-osmotic with the cell contents, across a specific membrane, and in addition, maintains the tone of the membrane, i.e., no solvent movement across the membrane. Thus, 2% boric acid solution is iso-osmotic with blood but it behaves like a hypotonic solution with erythrocytes while it is both iso-osmotic and isotonic with respect to the mucous membrane of the eye.

It has been also observed that hypertonic and hypotonic salt solutions tend to irritate sensitive tissue and cause pain when applied to mucous membranes of the eye, ear, and nose, etc., whereas isotonic solution causes no tissue

irritation when it comes in contact with the tissue. Obviously, the tonicity of formulations that come in to direct contact with blood, muscle, eye, nose, and delicate tissues is critical. Therefore, the issue of tonicity is important in small- and large-volume injectables, ophthalmic products, and products intended for tissue irrigation. The degree of tissue irritation or hemolysis or crenation observed depends on the degree of deviation from isotonicity, the volume injected, the speed of injection, the concentration of the solutes in the injection, and the nature of the membrane. The parenteral and ophthalmic formulations are therefore adjusted to isotonicity if possible. Hypotonic solutions can be easily adjusted to isotonicity by adding solutes such as dextrose or sodium chloride, commonly used for this purpose. However, at times, the formulation may be hypertonic and may have to be diluted with water to maintain isotonicity. This dilution of the hypertonic solution may be precluded owing to other limitations such as poor aqueous solubility of the drug. In such a case, the hypertonic solution can be administered slowly in small volumes into a large vein such as the subclavian vein in which the formulation will be diluted and distributed rapidly, minimizing chances of crenation of erythrocytes, pain, and tissue irritation on injection. It has also been observed that minor deviations such as 10% from isotonicity may result in no effect or only temporary effects at the site of injection. However, the effects of deviation from isotonicity of large-volume parenterals can be fairly severe and, thus, parenteral nutrient solutions and infusions of large volume need to be adjusted to isotonicity. Large-volume infusion of hypotonic solutions has been observed to cause effects ranging from hemolysis to water-retention problems such as convulsions and pulmonary edema. This was exemplified by the recent report of 10 episodes of hemolysis, with two patients exhibiting significant hemolysis and renal insufficiency resulting in one death. These severe episodes of hemolysis occurred because of the large volume infusion of 25% human albumin diluted with sterile water instead of with isotonic sodium chloride for therapeutic plasma exchange (1). In contrast, large-volume infusion of hypertonic solutions can result in severe conditions such as intracellular dehydration, osmotic diuresis, hyperglycemia, glycosuria, dehydration from loss of water, and coma. Also, hypertonic solution infusion should be terminated gradually to avoid sudden changes in osmotic pressure. In summary, any formulation that comes in to contact with sensitive tissues of the human body needs to be adjusted to isotonicity to minimize any adverse effects. To be able to adjust the formulation to isotonicity, a method to measure the tonicity and/or the osmotic pressure of the formulations has to be used. The methods to measure tonicity or

osmotic pressure of solutions are reviewed briefly as below.

MEASUREMENT OF TONICITY OF SOLUTIONS

The most direct method for measurement of tonicity obviously would be to observe changes in erythrocytes on mixing solution with blood. If hemolysis or crenation or a marked change in the appearance of erythrocytes occurs, the solution is not isotonic. If the cells retain their normal size and shape, the solution is isotonic. Grosicki and Husa used this method early on; however, one has to be mindful of the fact that solutions may be iso-osmotic with erythrocyte contents, yet may cause hemolysis because solutes such as boric acid are permeable through erythrocyte membrane and, thus, solution is not isotonic (2). Therefore, Grosicki and Husa recommended that the word isotonic should be used with reference to solutions having equal osmotic pressures with respect to a particular membrane (2). Because hemolysis due to hypotonic solution results in release of oxyhemoglobin directly proportional to the number of cells hemolyzed, a quantitative method has been developed to calculate osmotic pressure and the van't Hoff *i* factor noted above. A limitation of observing changes in erythrocytes as a measure of tonicity is the fact that the specific chemical interaction of the solute with the cell, pH of the solution, presence of solvents, lipid solubility of the solute, and denaturant activity of solute may have influences on the cell membrane and, thus, osmotic pressure differences alone are not responsible for hemolysis. Furthermore, it was shown recently that hemolysis is related to the contact time in addition to hypotonicity of the formulation (3). To overcome this limitation, some investigators have used measurements of erythrocyte cell volumes as a function of tonicity of solution, which influence solvent (water) uptake or loss from erythrocytes. This method is more sensitive, objective, and reliable than observation of hemolysis. Recently, a method using fluorescence anisotropy for fluidity of erythrocyte membranes demonstrated differences between hypotonic and isotonic solutions (4). However, the method is involving, and more data need to be obtained to correlate tonicity with fluidity of the membrane to be reliable.

An alternative approach is based on the theoretical foundation described earlier for the colligative properties. If the solution is isotonic with blood, its osmotic pressure, vapor pressure, boiling-point elevation, and freezing-point depression should also be identical to those of blood. Thus, to measure isotonicity, one has to measure the osmotic

pressure of the solution and compare it with the known value for blood. However, the accurate measurement of osmotic pressure is difficult and cumbersome. If a solution is separated from blood by a true semipermeable membrane, the resulting pressure due to solvent flow (the head) is accurately measurable, but the solvent flow dilutes the solution, thus not allowing one to know the concentration of the dissolved solute. An alternative is to apply pressure to the solution side of the membrane to prevent osmotic solvent flow. In 1877, Pfeffer used this method to measure osmotic pressure of sugar solutions. With the advances in the technology, sensitive pressure transducers, and synthetic polymer membranes, this method can be improved. However, results of the search for a true semipermeable membrane are still elusive, and this method is still cumbersome and inconvenient. The measurement of osmotic pressure using this method has been applied successfully to colloidal solution of proteins to measure their molecular weight because they are of relatively large molecular weight and are impermeable across number of membranes. Numerous instruments, known as osmometers, are commercially available to measure osmotic pressure (5,6). Only the Knauer membrane osmometer and colloid osmometer are true osmometers using a semipermeable membrane (5). Vapor pressure osmometers such as the Wescor osmometer, using the principle of vapor pressure lowering should not be called osmometers. These types of instruments measure the vapor pressure using the isopiestic method, or the thermoelectric method, or the measurement of the dew point of unknown solution in comparison with a standard, and then calculate osmotic pressure and osmolality using the theory of colligative properties. These instruments require a few microliters, and the method is fairly precise, simple, and totally automated. The presence of a volatile solvent such as ethanol will create problem with this method because the inherent assumption is that only water is present in the vapor phase. This can be a serious limitation because many parenteral and, ophthalmic formulations contain organic solvents for the purposes of drug solubility and, sometimes of stability. Commercial osmometers of this type have been found to measure osmolalities in the range of 100–3000 mmol/kg reliably.

Boiling-point elevation can also be used to measure osmotic pressure and tonicity of a solution using just a reflux condenser and a thermometer. The commercially available instrument is the Cottrell boiling-point apparatus. However, this method is affected by the ambient barometric pressure and the presence of volatile solvents in the solution.

Osmometers based on the freezing-point depression are the most commonly and widely used instruments for measurements of tonicity because of the simplicity,

reliability, and ease of use. Freezing-point depression of solutions of a number of drugs at various concentrations has already been determined, and thus, an extensive database is available for adjustment of tonicity of solutions of these drugs, as addressed below. The freezing-point depression of a solution can be simply measured using a salt–ice bath, Dewars flask, and Beckmann's thermometer. Numerous commercial instruments requiring small quantities of solution such as Osmette from Precision Systems that use the principle of Beckmann's freezing-point method are now available. One of the problems with this method is the disengagement of ice and the need for determination of the actual equilibrium freezing point. The latter limitation can be overcome by use of the equilibrium method, in which solid solvent (ice) is placed in contact with solution (aq.) and the freezing point measured and compared with that of the pure solvent (water) in contact with the solid solvent (ice). Also, one has to consider the presence of other solvents in influencing the freezing-point depression. The freezing-point depression method is precise to the extent that the differences in freezing points of two systems within $\pm 0.0002^{\circ}\text{C}$ can be measured. Freezing-point osmometry can be used for all samples with osmolalities less than 550 mmol/kg, including those that contain volatile solutes (6). Once the freezing point of the solution is known, inert solute such as sodium chloride is added to match the freezing point of solution with that of blood and lacrimal fluids. After considerable debate and experimentation, it is now well-established that -0.52°C is the freezing point of blood and lacrimal fluids, following the work of Lund et al. (7). This is also the freezing point of 0.9% sodium chloride solution, which is therefore considered to be isotonic with both blood and lacrimal secretions. Therefore, to determine the tonicity of a solution, one has to measure its freezing-point depression and compare it with that of blood (-0.52°C). The freezing-point depressions of a number of drugs are listed in Table 1. A more comprehensive list of the freezing-point depressions of various concentrations of drugs can be found in The Merck Index, Remington's Pharmaceutical Sciences, and other literature sources listed in the Bibliography. An important consideration when using this method is that although all the solutes present in solution contribute to its freezing-point depression, those that permeate the biological membrane will not maintain the tone, for example, boric acid. In addition, association of solute molecules by processes such as complexation and micellar association, which are temperature-dependent, may have to be considered. The viscosity and presence of suspended particles can also affect the freezing point by altering the crystallization of the solvent. Nevertheless, freezing-point

^aValues vary somewhat with concentration, and those in the table are for 1 to 3% solutions of the drugs in most instances.

A more comprehensive table of E and T_f values is found in Ref. 8.

^b MW is the molecular weight of the drug.

^c $T_f^{1\%}$ is the freezing point depression of a 1% solution of the drug.

^d L_{iso} is the molar freezing point depression of the drug at a concentration approximately isotonic with blood and lacrimal fluid.

^e E is the sodium chloride equivalent of the drug.

^f V is the volume in milliliters of isotonic solution that can be prepared by adding water to 0.3 g of the drug (the weight of drug in one fluid ounce of a 1% solution).

(Adapted with modifications from Ref. 9.)

depression has become popular because of its simplicity, reliability, and availability of commercial instruments. The methods of osmometry, the technology, and the limitations inherent in each method have been reviewed recently (5, 6) and should be consulted for more details.

Based on the theory of colligative properties and the principles of osmometry, it is understood that osmometer will read osmolalities and not osmolarities because colligative properties are directly proportional to the total solute concentration expressed in molality (see Eqs. 1–16).

The relationship between osmolality and osmolarity and its significance can be found in the Remington's Pharmaceutical Sciences and in a review article by Deardorff (10). However, it is more convenient to use osmolarity because it is based on weight/volume rather than on weight/weight as in osmolality. The U.S. Pharmacopeia also recommends that the labeling of parenteral and ophthalmic formulation should list osmolarity while the experimentally determined quantity is osmolality. Methods to convert osmolality to osmolarity using determinations of solution density and solute content (11, 12) or using partial molal volume of solute and solvent have been described (13, 14).

THEORETICAL METHOD TO CALCULATE TONICITY USING L_{iso} VALUE

In the discussion above of colligative properties of electrolytes, the equations were modified by introduction of the van't Hoff i factor as shown in Eq. 16. Because the freezing-point depressions of strong and weak electrolytes are always greater than those calculated from Eq. 9, because of different degrees of ionization and interionic interaction, a new factor, $L = iK_f$, is introduced. The L value obtained from freezing-point depression of a solution of a particular type of electrolyte at a molar concentration (c) that is isotonic with blood is defined as L_{iso} ($L_{\text{iso}} = 0.52^\circ/c$). For example, the L_{iso} value for an isotonic sodium chloride solution (0.9%w/v) is 3.4, and its freezing-point depression is 0.52°C . Because the colligative properties are independent of the chemical nature of the electrolyte and the interionic interactions in dilute solutions are similar, all electrolytes of the same type will have identical L_{iso} values. Therefore, all nonelectrolytes have $L_{\text{iso}} = 1.9$, whereas uni-univalent electrolyte's $L_{\text{iso}} = 3.4$ and triunivalent electrolyte's $L_{\text{iso}} = 6.0$. Thus, if the ionic nature of the solute and its molecular weight are known, using the appropriate L_{iso} value, freezing-point depression can be calculated for a solution of a given concentration. The average L_{iso} values for all types of solutes are available in the literature (9). This method is simple and does not require experimentation, but it is only approximate, with potential for some error. Also, one has to know the ionic nature of the solute, which can be difficult to determine for a new drug compound with a complex structure.

METHODS OF ADJUSTING TONICITY

From the theoretical background presented above, one can easily devise his or her own methods to adjust tonicity of

solutions using the principles of colligative properties. However, in the practice of pharmacy, a number of simple methods to adjust tonicity of formulation in a prescription order on an extemporaneous basis were developed to help the pharmacist. The methods of adjusting tonicity could be classified into two types. In class I methods, some inert substance such as sodium chloride or dextrose is added to the solution to lower its freezing point to match that of blood (-0.52°C) i.e., made isotonic by the addition of inert excipient. In class II methods, a calculated quantity of water is added to the total solute content (drug) of the prescription to make it isotonic, which is then diluted with sufficient isotonic diluting solution to bring it to the final volume. These methods are explained below, followed by a simple example illustrating the method. However, the assumptions inherent in all the methods need to be considered carefully. The first assumption is that colligative properties are additive for mixture of solutes and that they are related linearly to their concentration expressed in molarity, molality, or in percentages. This assumption is true in dilute solutions of nonelectrolytes and electrolytes. However, when dealing with concentrated solutions, this assumption may not be valid. In cases of chemical interaction, association, complexation, or micellar interaction among solutes in solution, the colligative properties of solutes may not be additive. The second assumption is that they consider all solutes present in solution to be contributing to its tonicity. However, it is known from the discussion above that all biological membranes are not truly semipermeable, and thus, some solutes will not contribute to the tonicity of the solution across that membrane, for example, boric acid across erythrocytes membrane. Nevertheless, the errors introduced are small, and slight deviations from isotonicity on either side do not result in significant adverse effects. In the literature, one may also find methods known as the L value method or the L_{iso} method, which are identical to the theoretical method described above for solutes, for which one can calculate the freezing-point depression based on molecular weight and ionic nature. By knowing the freezing-point depression, any of the class I or class II methods can then be used to adjust their solution to isotonicity.

Class I Methods

Freezing-point depression method (cryoscopic method)

The freezing-point depression of a number of drugs and excipients, either experimentally determined by the method described above or calculated theoretically using the L_{iso} method, is available in the literature (8, 9, 15). Table 1 (adapted from Ref. 9.) lists the freezing point

depression of 1% solution of various drugs. Basically, from the percentage of drug present in solution, the freezing point of the solution is calculated. This number is then subtracted from the freezing point of blood (-0.52°C) to obtain the freezing-point depression to be achieved by the addition of sodium chloride. Knowing that 0.9% sodium chloride is isotonic and freezes at -0.52°C , the amount of sodium chloride to be added is calculated as shown in the example below.

Example 1: Calculate the amount of sodium chloride needed to prepare 100 ml of 2% isotonic physostigmine salicylate solution.

Freezing-point depression of 2% physostigmine salicylate = $2 \times 0.09^{\circ}\text{C} = 0.18^{\circ}\text{C}$ (Table 1). Therefore, the freezing-point depression to be achieved by adding sodium chloride = $0.52^{\circ} - 0.18^{\circ}\text{C} = 0.34^{\circ}\text{C}$. Sodium chloride (0.9%) produces a freezing-point depression of -0.52°C ; therefore, the percentage of sodium chloride needed = $(0.34^{\circ}\text{C}/0.52^{\circ}\text{C}) \times 0.9\% = 0.59\% = 0.59 \text{ g}/100 \text{ ml}$.

Sodium chloride equivalent (E) method

The sodium chloride equivalent (E) is the amount of sodium chloride equivalent to 1 g of the drug in exerting the same osmotic effect. The E value for a new drug can be calculated from its L_{iso} value or from the freezing-point depression as shown below.

The freezing-point depression of a 1 g/L-solution of a new drug can be expressed as:

$$\Delta T_f = L_{\text{iso}} \frac{1 \text{ g}}{MW} \quad (17)$$

By definition, E gram of sodium chloride ($MW = 58.45$ and $L_{\text{iso}} = 3.4$) in 1 L will have similar freezing-point depression as shown below:

$$\Delta T_f = 3.4 \frac{E \text{ g}}{58.45} \quad (18)$$

Therefore, equating Eqs. 17 and 18, results in the following equation for E :

$$E = 17 \frac{L_{\text{iso}}}{MW} \quad (19)$$

Wells developed a nomogram based on the above equation to readily calculate E values from the MW and L_{iso} value of the drug (16). Thus, the E value for physostigmine salicylate ($MW = 413.46$) calculated using $L_{\text{iso}} = 3.4$ for a uni-univalent electrolyte is equal to 0.14, which is close to 0.16 (E value) in Table 1. This small deviation is attributable to the difference between the experimentally determined L_{iso} (3.9) of physostigmine salicylate and the theoretical value of 3.4 for a uni-univalent

electrolyte. By knowing the E value, the solution can be adjusted to isotonicity as shown below.

Example 2: Calculate the amount of sodium chloride needed to prepare 100 ml of 2% isotonic physostigmine salicylate solution.

Physostigmine salicylate (2 g/100 ml) is equivalent to $2 \times 0.16 (E) = 0.32 \text{ g}/100 \text{ ml}$ of sodium chloride. Therefore, 0.58 g (0.9–0.32 g) of sodium chloride has to be added to 100 ml of this solution to make it isotonic.

Note that the answers given by the two methods are not identical, but very close.

Class II Methods

The class II methods involve the calculation of a quantity of water needed to make an isotonic solution for a given amount of drug, followed by dilution with an isotonic solution to make up the volume. These methods were developed to enable pharmacists to prepare parenteral and ophthalmic formulations with simplicity and ease.

The White-Vincent method

In this method, the weight of the drug (w) is first multiplied by its sodium chloride (E) to obtain the quantity of sodium chloride osmotically equivalent to weight per gram of drug (17). Because 0.9 g of sodium chloride dissolved in 100 ml results in an isotonic solution, the volume of isotonic solution that can be prepared from weight per gram of drug is given by the following equation:

$$V = wE \frac{100}{0.9} = 111.1 wE \quad (20)$$

Thus, dissolving weight per gram of drug in V ml of water will result in an isotonic solution that can be further diluted with isotonic solutions such as 0.9% sodium chloride or isotonic dextrose solution to make up the volume. The method can be illustrated by the following example.

Example 3: Prepare 100 ml of 2% physostigmine salicylate solution isotonic with blood.

Using Eq. 20 and E of physostigmine salicylate = 0.16 from Table 1, the volume of water needed to prepare isotonic solution, $V = 2 \text{ g} \times 0.16 \times 111.1 \text{ ml/g} = 35.55 \text{ ml}$. This solution can be diluted with 64.45 ml of any isotonic diluting solution to obtain 100 ml of 2% isotonic physostigmine salicylate solution. To verify the results, if we assume that we dilute the above solution with 64.45 ml of isotonic sodium chloride solution, the equivalent amount of sodium chloride added is 0.58 g, which matches with results obtained using the class I methods.

The Sprowls method

In the early days of pharmacy practice, many prescriptions were written to prepare one fluid ounce of a 1% drug solution,

thus, the amount of drug ($w = 0.3$ g) and the final volume were fixed (one fluid ounce or 30 ml). Sprowls, recognizing this fact, suggested a modification of the White–Vincent method to further simplify the calculations for the practicing pharmacist (18). In this method, the amount of drug is fixed at 0.3 g (30 ml of 1% solution), and the volume of water required to prepare the isotonic solution is calculated using Eq. 20 and listed in a table such as column 4 in Table 1 for all drugs that are commonly used in parenteral and ophthalmic formulations and for which sodium chloride equivalents are known. The pharmacist then makes up the volume of the preparation to 30 ml with an isotonic diluting solution to fill the prescription. For example, if one fluid ounce of 1% physostigmine salicylate solution is to be prepared, from Table 1, column 4, we recognize that 5.3 ml of water is required for 0.3 g of physostigmine salicylate to prepare an isotonic solution. After the preparation of this 5.3-ml solution, it can be diluted with any isotonic diluting solution to make up the volume to one fluid ounce. If one needed to prepare 100 ml of a 1% solution, the volume of water (V) should be multiplied by 3.33 to obtain the amount of water necessary to make it isotonic.

FUTURE DIRECTIONS

The theory of colligative properties is well-understood and successfully applied to parenteral formulations for making them isotonic and, thus, safe and acceptable. The techniques of osmometry have been refined, and now instruments that can estimate freezing-point depression, vapor pressure, or osmotic pressure from microliter quantities of samples in a few minutes are commercially available. At the same time, very few pharmacists are required to compound prescriptions requiring the knowledge of the various methods of adjustments of tonicity. Because of ever-increasing complexities in the structure of new drug entities, there is an increasing problem of their inadequate aqueous solubility, exemplified by drugs such as Cyclosporine and Taxol. A number of organic solvents and new classes of surfactants are being developed and used to aid in solubilization and, thus, in the formulation of these drugs for parenteral administration. The issue of tonicity needs to be addressed from this perspective because organic solvents and the surfactants behave differently in solution than do the traditional solutes whose characteristics in solution are well-understood. Also, dispersed systems such as nanocapsules, liposomes, and microemulsions are being developed as parenteral formulations. The colligative properties of these systems need to be investigated too. There is an increasing concern regarding tissue irritation and muscle injury at the

site of injection resulting from formulations. With the advent of biotechnology, more peptide and protein drugs are in clinical trials than before, and, also, gene therapy is being considered for few diseases. The parenteral formulations of these newer drugs are more complex to maintain the integrity of their higher-order structure. Therefore, the issue of tonicity needs to be revisited with a newer approach and from a different perspective.

Tooling for Tableting

Annette Bauer-Brandl

The University of Tromsø, Tromsø, Norway

INTRODUCTION

Introducing high-speed tableting in 24-hr shifts has tremendously increased productivity, which in turn places heavy demands not only on the tablet presses and the compressibility of the tableting materials but also on precision with respect to dimensions and the wear resistance of the toolings (punch and die sets). Furthermore, in many cases of high tableting-speeds, adhesiveness of tablets to the toolings becomes a problem in the course of long-term production. Tableting materials need to be optimized in line with new demands. At the same time, tooling requirements with respect to adhesion-reducing finish have become more important than ever.

Special attention must be paid to handling and maintaining the tool sets during their entire lifetime. Not only does timely mechanical work-over prolong their total lifetime, but also trace patterns of wear on the tooling itself can be indicative of numerous different events during production, inter alia pressures that are generally too high, inadequate lubrication resulting in excessive friction, blockage of pressure rollers, tilted punches, or dies. Furthermore, worn-out punches not only affect the quality of the tablets (increased variation of mass, reduced surface shininess etc.), but can also cause serious problems in the process (powder loss with dust sticking to lubrication oil as well as excessive wear of the tablet press itself). Scratched surfaces can lead to grave problems with tablets sticking to the punches at the discharge point, making tablet production impossible. A deviation in the length of a lower punch translates directly into mass variability in the tablet batch; variation in the length of the entire set also leads to varying compression forces and consequently affects the dissolution properties of the tablets.

On the other hand, tablet tooling design opens up for many possibilities for overcoming common tableting problems that cannot be solved by modifying the materials or the compression process, such as lubrication problems which in general are also a function of tooling size and shape.

BACKGROUND

In the following text, only examples and principles will be discussed. Mentioning or omitting a specific make or

model does not constitute any value judgment. Comprehensive recommended publications are “The Tablet Specification Manual”^[1] with respect to technical and practical problems of tooling, and for all aspects of tableting including development of tableting materials, optimization of compression cycles, and handling of tooling “Die Tablette.”^[2]

GENERAL TERMINOLOGY OF TOOLING

A set of tooling consists of upper punch, lower punch, and die. The upper punch has a shorter stem; the lower punch stem is longer because it travels longer distances up and down in the die for filling, compression, and ejection, thereby sealing the die hole from below during the entire process of compression.

In single-punch tablet presses (reciprocating tablet presses), the punches are fixed to the punch holders which travel up and down, and in many cases fixation screws are used. Each make has its own holder design for punches and dies, and consequently for the tooling sets as well. Therefore little can be said in general terms, but it would appear that on the whole the remarks on the rotary press tooling apply correspondingly.

In rotary tablet presses, only the dies are fixed in the die table, whereas the punches are vertically mobile and are not fixed to a holder. They slide up and down in the turret bores, driven by cam tracks guiding the punch heads. The dwell time, i.e., the period during which the tablet is under full compression, is determined by the diameter of the flat part of the punch head.

The amount of clearance (space) between interacting parts like punch/die and barrel/turret guide, depends on the tolerance range (deviation from theoretical dimensions due to practical manufacturing reasons) of tooling dimensions. The clearance between the die wall and the punch tip affects the tableting process as well as the mechanical properties of the finished product: while the powder is compressed, air needs to be released, and when the compressed tablet is moved upwards within the die bore, friction on the die walls is affected by the clearance.

A deviation in the overall length or the working length of a lower punch in a set of punches for a rotary press translates directly into mass variability in the tablet batch;

a deviation of not more than ± 0.1 mm can lead to a mass variability of 2% in the case of small tablets. Moreover, variability of the lengths of both lower and upper punches affects the variability of compression forces with consequences for tablet dimensions, their tensile strength, and dissolution behavior. In the case of a short lower and upper punch, overfilling would not necessarily lead to an increased force signal.^[3]

TOOLING FOR SINGLE-PUNCH PRESSES AND COMPACTION SIMULATORS

Nowadays, single-punch presses are, in general, only used in R&D, but hardly in pharmaceutical production. Useful research tools are instrumented special hydraulic presses, “compaction simulators,” which allow for online measurements of forces and displacements during the tableting process. Compaction simulators are in many cases designed to accommodate standard single-punch tooling, which is specific for each machine type, e.g., Korsch EK0 (<http://www.korsch.de>), Kilian SP300 (<http://ourworld.compuserve.com/homepages/Kilian>). Dimensions of the tooling and tolerances thereof are up to the press and tooling manufacturer.

Two-piece configuration—i.e., a punch with interchangeable punch tips—is common for single-punch presses as, in general, single-punch tooling is less exposed to abrasion and—compared to tooling for rotary presses—can relatively be aligned easily. In the case of two-piece tools, the lower punch tips are not rigidly fixed but allow for some tilting in order to avoid excess friction in the die bore. Multiple tools comprise several punch tips on a single holder in order to increase productivity. They have been common for single-punch presses used in small-scale production, particularly in the form of multipiece tools, where any cracked tip can be exchanged separately.

TOOLING FOR ROTARY TABLET PRESSES

Fig. 1 shows the general terminology of punches and dies for rotary tablet presses. The punch consists of head, neck, barrel, and stem. The barrel diameter and the overall length are determined by the machine turret dimensions. The working length (i.e., overall length minus any cup depth at the punch tip) determines thickness and mass of the tablets and needs to be controlled regularly. The variation in working length should be within $\pm 10 \mu\text{m}$ to ensure low variability of tablet properties. The die depth should also be accurately cut in order to guarantee a flush fitting with the die table.

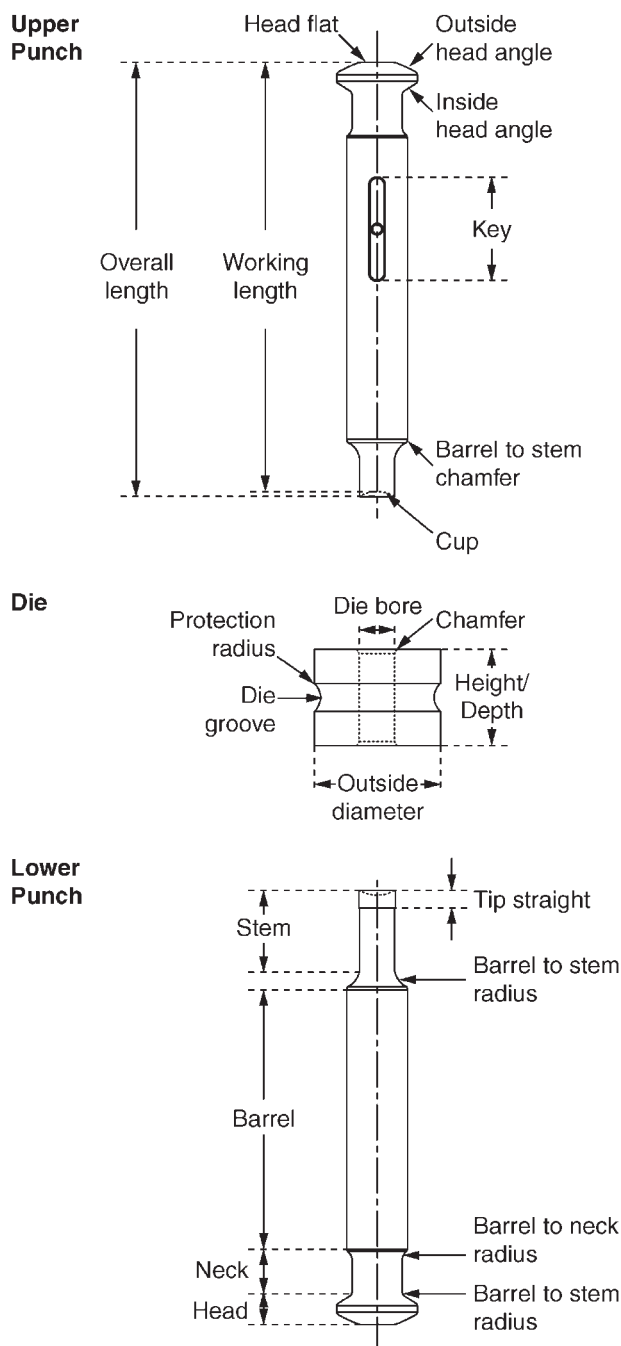

Fig. 1 General terminology of tooling (sets of upper and lower punches and dies) for rotary tablet presses.

International Standards

Standardization of tooling dimensions has been agreed to facilitate interchangeability between presses and to reduce the number of spare parts. In many cases, a certain press is available with different turrets in order to standardize tooling within a tablet manufacturing company irrespective of

Tooling for Tableting

3

the make of tablet presses used in R&D and production, respectively. A special turret for R&D on which all standard tooling can be used on one and the same turret is available from Pharmachine India (<http://www.serenader.com/pharmachine/develop.asp>). It allows to interchange punches and dies of any sizes for trial compression.

There are two main standards: 1) B-tools with subcategories EU19 (Europe)/TSM 19 (USA)/Japan Norm; 2) D-Tooling, also called EU1, TSM 1, which are classified according to the dimensions of the barrel diameter, overall length, and the overall diameter of the punch head. Fig. 2 compares dimensions of B- and D-tooling. D-tooling is thicker than B-tooling; European toolings (both B- and D-types) are longer compared to TSM types. Fig. 3 explains terminology of the punch head in order to differentiate subcategories of B- and D-toolings. The head angle or head radius (in the case of “domed heads”), respectively, determines the lead under the compression roller. The head flat determines the dwell time of the compression event (i.e., the period during which the tablet is under maximum pressure), which should preferably be long so as to yield mechanically resistant tablets. The head flat must in all cases be smaller in diameter than the neck in order to guarantee pressure transmission onto the whole punch. Neck shape and neck

Fig. 3 Punch head terminology.

Fig. 2 Standard sizes of B- and D-tooling. Comparison of the respective subcategories according to the European standard and the U.S. standard (TSM).

diameter are determined by the dimensions of the cam track. The head thickness needs to be precisely cut in order to ensure a smooth gliding of the punches through the cam track and, in the case of lower punches, to guarantee a reproducible dosing of granule in the die as well. Three subcategories of B-tooling according to the European and the US (TSM) standard as well as the Japanese norm are compared in Fig. 4(a) and (b) in general terms, and their respective head dimensions are accurately depicted and closely compared in Fig. 5(a). The respective head dimensions for the three subcategories of D-tooling are shown in Fig. 5(b).

There is another head shape to the D-tooling called Fette EU1 441 (<http://www.fette.de>), which is characterized by the absence of a neck and a larger head diameter (38.00 mm) allowing for increased dwell times (see “Special Tooling”).

A further subcategory of B-tooling, which is referred to as B2-type (Stokes, <http://www.stokesdti.com>), has the same barrel diameter as the standard B-type, but the overall length of the lower punch is smaller (Fig. 6). B2 is used on some older presses, but not manufactured any more. There is yet another variation on standard B-type tooling, where the overall diameter of the die is smaller (Fig. 7). The die diameter determines the maximum tablet

Fig. 4 Subcategories of B-tooling, defined by overall length and head shape: (a) U.S. (TSM) standard, and Japan norm; (b) European norm (domed head).

Fig. 6 Subcategories of B-tooling: B2 tooling compared to standard B.

diameter as well as the maximum number of die bores in the case of multiple tools. A larger die is more resistant although pressure is not directly applied to it but only by lateral extension. The terminology of standard dies is explained in Fig. 8(a). The height (depth) of the die ensures a flush fitting with the die table. The overall die diameter—nominal size and manufacturing tolerances—enables a tight fit in the turret avoiding lateral movement, which is also supported by the die groove accommodating the locking screws. A protection radius or protection

shoulder prevents damage to the die locking screw or scoring of the die pockets in the turret caused by burrs or sharp edges on the die. The die bore should be made as close to its nominal size as possible because it is this, which determines the tablet size, not the punches. A bore chamfer provides a lead for the upper punch to enter the die.

Any clearance between the die wall and the punch affects the tableting behavior, as entrapped air will escape through the gap when pressure is applied. Fig. 9 presents the terminology. Table 1 summarizes manufacturing tolerances of punches and dies as well as the clearance between them.

Fig. 8 Die terminology: (a) Standard die. (b) Tapered die.

Fig. 9 Terminology of tolerances and clearances between punches and dies.

Die bore tapers with a conical opening as is depicted in Fig. 8(b) have the same effect as the clearance. Tapered dies are more expensive than standard dies. Tapers can be applied to both ends of the bore to allow for an inversion

<i>a) Tolerances for B- and D-type round tooling:</i>		
Upper punch	Overall length	$\pm 50 \mu\text{m}$
	Working length	$\pm 10 \mu\text{m}$
	Head diameter	$+ 0 \mu\text{m} - 100 \mu\text{m}$
Lower punch	Overall length	$\pm 50 \mu\text{m}$
	Working length	$\pm 10 \mu\text{m}$
	Head diameter	$+ 0 \mu\text{m} - 100 \mu\text{m}$
Die	Height	$\pm 10 \mu\text{m}$
	Diameter	$+ 0 \mu\text{m} - 10 \mu\text{m}$
	Concentricity	$25 \mu\text{m}$
<i>b) Tolerances and clearances for round and shaped tooling</i>		
	Round tooling (μm)	Shaped tooling (μm)
Nominal die bore size	$+ 10 - 0$	$+ 20 - 0$
Upper punch tip tolerance	$- 40$	$- 60$
Lower punch tip tolerance	$- 20$	$- 40$
Upper punch/die minimum clearance	40	40
Upper punch/die maximum clearance	60	80
Lower punch/die minimum clearance	20	20
Lower punch/die maximum clearance	40	60

Fig. 10 Keys on punches: terminology.

of the dies. Tapered dies not only let air escape, but also assist ejection as the stress is gradually released by ejecting to an increasing diameter thereby preventing capping and generally increasing the tensile strength of the tablets. Furthermore, their use also allows higher machine speeds.

Shaped punches—all other shapes than round ones—and multtip punches need to have keys on their barrel in order to prevent any rotation. The terminology of keys is explained in Fig. 10. Keys are available in two configurations: the Woodroff key and the flat key (European key) can be distinguished by the shape of the slot milled into the barrel where the key is in many cases screwed into position. The vertical position of the key on the punch barrel and the length of the key itself are determined by the turret dimensions in such a way as to allow for clearance in the punch-guide keyways. The optimum angle of the key with respect to tablet shape is determined by the rotation direction of the tableting machine and the design of the take-off fence at the discharge point with respect to the punch tip, and therefore not standardized. Tablets hitting the fence with a corner should be avoided; they should rather hit it with a flat face in order to ensure proper discharge without fragmentation. Common configurations for punch keys and their lengths can be found in Tablet Specification Manual.^[1]

Barrel flutes, usually on round upper and lower punches, are vertical sharp-edged grooves along the length of the punch barrel. During production, they would rotate and thereby scrape off possible depositions of material in the punch guideways.

Fig. 11 Comparison of shapes and dimensions of well-known toolings.

Several types of dust caps and sealings fitted to the barrel-to-stem chamfer (e.g., Ref. 4) are available to prevent contamination of the tablets by machine oil dripping from the upper punch. Alternatively, punch bellows in silicone rubber fitted into special seal grooves for Euro-standard are available (e.g., from Holland, <http://www.iholland.co.uk>).

SPECIAL TOOLING

Some makes of tablet presses have their own tooling specifications allowing for longer dwell times and higher compression forces, such as the Fette EU1 441 mentioned earlier, and Kilian 25/32, with subtypes in die shape, i.e., grooved and slotted, which are depicted together with standard types in a tooling identification chart (Fig. 11). Most tablet presses from the manufacturers cited are alternatively available with turrets for standard size tooling.

Two-piece configurations with interchangeable punch tips can also be used in punches for rotary presses. Special care and experience are necessary as these punches can be difficult to assemble and align; they are mostly used with multiple tools in order to increase productivity, thus offsetting additional costs.

Korsch (www.korsch.de) has a special machine for solving sticking problems, where the entire punches are rotated before and after the compression phase in order to prevent adhesion. These punches have a cogwheel around their neck.

From Manesty (<http://www.manesty.com>) a special rotating-head tooling is available which enables the punch head of shaped tooling to rotate in order to increase the lifetime of punches and cams.

By IMA (<http://www.ima.it>), a special high-speed machine design has been developed. Feeding happens at the center, taking advantage of increasing centrifugal forces. This design requires special tooling, which is made in two pieces. This means that only the punch tips need to be changed, which saves time in this special machine.^[5]

Instrumented punches and dies, which enable online measurement of forces on the punch and relative displacement or acceleration, electrical resistance, and acoustic release as well as measurement of die wall forces, are special tools used exclusively in research; they are discussed in a separate chapter.

PUNCH TIPS

First of all, one has to make a general distinction between round and shaped tablets. The nomenclature of tablet shapes of round flat and convex tablets as well as the respective punch tip forms are shown in Fig. 12. The tip edge design of the punch and the forces it is exposed to during compression, and the resulting deflection forces are shown in Fig. 13. It is impossible to maintain an infinite sharp edge as this would wear off immediately; the figure also shows how a land is introduced by polishing the punch tip in order to increase its pressure tolerance. The land/cup connection can be designed as a sharp corner, a standard curvature (radius), or a blend radius.

Round tablet terminology

Fig. 12 Terminology of round tablets for flat-faced and convex tablets.

Sharp tip edge deformation

Tip deflection under load

Fig. 13 Punch tip edges: wear and deformation under load, effect on tablet shape and tip deflection.

Round tablet profile terminology can be found in Fig. 14.

Similarly, for shaped tablets, terminology is explained in Fig. 15, and well-known examples of shapes and profiles are depicted in Fig. 16.

In order to avoid sticking, it is recommended to avoid corners. Compared to the profile of the land/cup connection, an alteration of the common connection between the bevel and the flat by rounding the beveled edge of flat-faced punches, thus reducing the possibility of sticking of material to the sharp edge, has been proposed to reduce sticking problems.^[6]

Break lines are most often bisects or quadrisects, whereas engravings often comprise characters and graphic objects facilitating identification of the tablets. Engravings on tablets can be embossed or debossed (Fig. 17), the punch has to be the respective opposite, and the characters and figures are mirrored. In many cases, break lines and engravings trigger sticking problems. In order to quantify the pull-off force of a tablet sticking to a punch surface, a special instrumentation was developed^[7] and used for the optimization of the angle between the engravings and the surface.^[8] As sticking in most cases starts at the lateral faces of the engravings due to shear forces occurring there

Round tablet profiles

Fig. 14 Round tablet profiles. (Open ring tablet: From Notter, A. R. German Patent DE 4342146 C1, December 10, 1993.)

Shaped tablet terminology

Fig. 15 Terminology of shaped tablets: profiles of capsule-shaped (oblong) and oval tablets.

during compression, the authors quoted above generally recommend a small angle of the stroke to the surface (between 45 and 75° —as to the question of how to define the opening angle, see Fig. 18). This is in contrast to findings of Sabir, Evans, and Jain,^[9] who recommend an angle of 90° , but their study lacks conclusiveness as the steep angle tooling, unlike the reference tools, was chromium-plated. Waimer et al. used a cone for their measurements,^[7,8] and it can be assumed that engravings comprising a greater number of lateral faces per area would need even more attention. Empirically, it is recommended to avoid sharp corners as in characters like “A” and to use radii instead; tooling manufacturers have their special rounded character type sets (Fig. 18). For film coating, the profile of the engravings must be particularly flat-angled in order to ensure wetting with the coating material. The maximum area on the surface of the tablet that can be used for engravings depends on the cup depth.

Requirements for break lines have been increased during the past years. All break lines must ensure that the tablet breaks into equal parts and lines for decoration purposes are not legal any more. Guaranteeing

Fig. 16 Examples of well-known tablet shapes. (Courtesy of Ritter Pharmatechnik, D-Hamburg.)

Fig. 17 Embossing/debossing of engravings on tablets and punches.

Fig. 18 Terminology of engravings, exemplified by the character "A." (Courtesy of Ritter Pharmatechnik, D-Hamburg.)

a reproducible crack is not trivial as the powder located right under the break line is exposed to the highest compression stress and most compaction and is therefore in many cases mechanically strongest. Therefore, break lines should not be too deep, and notching of the outer tablet wall serves to ensure a defined crack line. Notching requires coves in the die wall and, consequently, punch rotation has to be prevented. Some typical standard bisect line types are shown in Fig. 19. The shape, angle, and depth of bisects with regard to the shaped tablet surface has been optimized in order to facilitate the breaking of tablets by pressing them against a hard pad with one finger (Fig. 19, lower line, and Figs. 20 and 21).

In bigger tablets other than those commonly used pharmaceutically, the requirements for reproducibility are lower, which, e.g., makes it possible to press a trough into the tablet surface so that a second mixture of tensides for dish-washing can be applied after tableting. The punch can be designed as an interchangeable cone made from synthetic material.^[10]

Multiple tools have several punch tips on one and the same barrel; the corresponding die has as many bores in order to increase productivity. One disadvantage results from the more delicate handling of the tools, but multiple tools are definitely useful for small tablets in order to increase productivity. Minitablets of 2 mm diameter are

Fig. 19 Forms of commonly used bisects. (Courtesy of Ritter Pharmatechnik, D-Hamburg.)

Fig. 20 Example of a pressure-sensitive quadrisect tablet. (Courtesy of Ritter Pharmatechnik, D-Hamburg.)

Fig. 21 Method for dividing pressure-sensitive tablets into equal parts.

produced as a substitute for pellets and offer the advantage of better reproducibility of filling into capsules as well as better reproducibility of their specific surface area, which is important for the coating process and the subsequent reproducible release of the active drug. Multiple punch tips are frequently manufactured as multiple tools in a several-piece punch design. A 19-fold punch set is available and working in standard production of minitabets. Up to 55-fold tooling has proved to function in experimental studies (<http://www.ritter-pharmatechnik.de>). The setup of the tiny tooling is depicted in Fig. 22.

MATERIALS, MANUFACTURE, FINISH, AND PRESSURE TOLERANCE

Materials and Manufacture

Steels are basically classified as carbon and alloy steels which are defined by national and international standards, e.g., ASTM and DIN. Carbon steels contain less than 1.65% manganese, 0.6% silicon, 0.6% copper, plus boron and deoxidizers as well as carbon as the principal additive increasing hardness. Manganese also increases hardness, particularly the ability to be hardened by tempering, and is present in all steels. Silicon acts as a deoxidizer. Alloy steels exceed these limits or contain additional elements, e.g., chromium, vanadium, tungsten, molybdenum, nickel, and cobalt. A high-nickel content increases resistance to corrosion caused by HCl released from drug salt.^[11] The composition of special steel types for tooling, their provenance, and their thermal treatment are part of the trade secret of tooling manufacturers.

A high abrasion resistance usually corresponds to high hardness of a steel type, whereas its ductility and toughness is low and vice versa: very hard tooling may

Fig. 22 Setup of multitools, left: minitabets, 2 mm diameter; right: triple-tool for 6-mm tablets. (Courtesy of Ritter Pharmatechnik, D-Hamburg.)

Table 2 Hardnesses of steel qualities used for tooling (Rockwell hardness)

Steel	S1(BS1)	S7	BD2 (D2)	BD3(D3)	440C stainless
Rc-hardness	54–56	54–58	58–60	58–60	56–58

fracture, ductile material may wear off quickly. Hardness and ductility do not only depend on the chemical composition of the steel but also on its heat-treatment (tempering). A second tempering procedure for punch tips, which is computer-controlled and carried out at high temperatures in a vacuum furnace, softens the material and prevents fracture.

Punches usually have a longer lifetime than dies if they are made from the same material; that is why manufacturers often choose different steel qualities. The surface of a die bore can become smoother or rougher during its use. The ejection force does not—apart from the composition of the tableting material and the compaction force—necessarily depend on roughness of the die wall, but to a high degree depends on the metal type of the die.^[12]

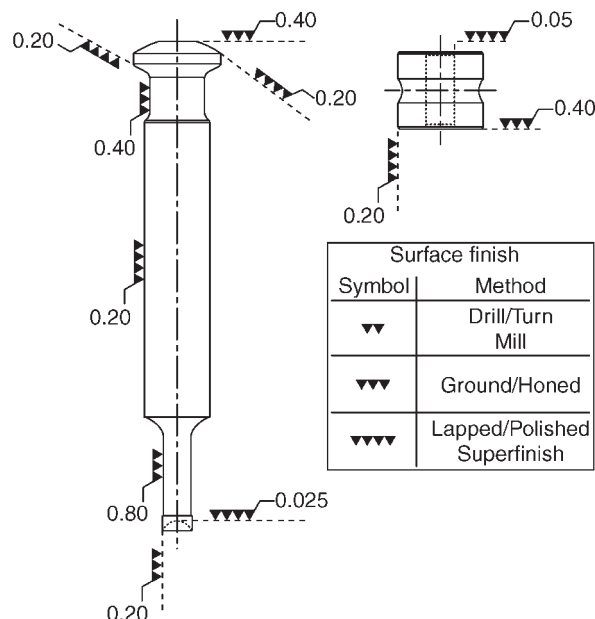

For specific tableting tasks, the tooling manufacturer will be able to provide optimum tool properties. It may be helpful in this respect to supply him with a sample of the tableting material in question.

Table 2 gives hardness characteristics of some steel qualities that are frequently used. 440C has the highest chromium content (17%), which increases wear resistance. D2 and D3 have a high-chromium content (12%) and are additionally carbon-rich (over 1.5%). Chromium and carbon together form stable carbide, which increases hardness. S1 contains tungsten (2%), which makes heat-treatment easier. More about steel qualities and international standardization thereof is available from steel manufacturers or the relevant authorities via the World Wide Web (e.g., <http://www.sz-metal.si>).

Finish

Adhesion, sticking, picking, and filming on punches and dies can in many cases be avoided by a suitable surface finish of the tooling. In some cases, the surface is smoothened during continuous use of punches, whereas in other cases, depending on the material compressed, e.g., in the case of crystalline lactose, small scratches may occur on the punch tips after a few thousand compression events.^[13] On those small scratches and defects in the surface, corrosion will start.

Tolerances for the surface finish of tooling are also specified by manufacturers and in international standards, see Fig. 23. Any roughness of the finishing is below 1 μm

**Fig. 23** Surface finish of punches; tolerances for top-to-valley differences (in μm).

peak-to-valley height, and particularly punch-tip faces and die bore walls are polished to achieve lower tolerances.

Coatings and Platings on Punch Tips

Reduced ejection forces can help to avoid both lamination and capping and give tablets a shiny surface as well as high mechanical strength. Internal lubrication (lubricants added to the tableting material) is counter-productive not only because its admixture is another critical step in production, but also because the most effective lubricants are hydrophobous and make the tablets softer and increase disintegration time as well as dissolution rate. Attempts to coat the tooling with fluid or solid lubricants just before each compression event are relatively complicated with respect to machinery, reproducibility, dust formation, and GMP demands, e.g., batch definition. In many cases, an easier alternative may be to apply a finish to the punches that reduces friction by special coating or plating of the punch tips so that ejection forces are reduced. Another reason for coating the punches may be to decrease the adhesiveness of tablets to the punches as this does not necessarily decrease with reduced ejection forces. It may also be necessary to increase corrosion resistance in cases where aggressive chemicals are compressed. A critical demand on all coatings and platings is their wear resistance. The thickness of the coat must be taken into account as it affects clearances and tolerances. As this is also a part of the trade secret of manufacturers and specialized companies, little is published on this subject.

Hard chromium plating is applied galvanically with a thickness of approximately $30\text{ }\mu\text{m}$. It should not be confused with blank chromium plating, which consists of several layers of other metals with a very thin chromium layer on top and is not suitable for tooling. Hard chromium platings, although appearing shiny and smooth, are more porous than the blank coatings, brittle, and in many cases not sufficiently wear-resistant. Moreover, any transition of traces of chromium into the product would be totally unacceptable for pharmaceutical use. Not in all cases do they have the desired effect with respect to sticking.^[14]

Nodular thin dense chromium is an FDA-approved coating which is applied to the entire punch and all its faces.

Chromium can be implanted into the surface in the form of chromium nitride at a depth of up to $1\text{ }\mu\text{m}$ by nitrogen ion bombardment of the surface. This treatment proved to have a favorable effect on sticking problems^[14] and makes the surface relatively wear-resistant. Titanium can be applied in the same way in the form of TiN. This treatment leaves the tools in a “bronzed” appearance because the surface is relatively rough as seen in the electron microscope. Increased hardness and greater wear and corrosion resistance is achieved, but the effect on friction is smaller than in the case of CrN.

Nickel–chromium–boron alloying coat applied on both punches and dies has been described^[15,16] and compared to untreated tools. Surprisingly, depending on the material under compression, the coating had the expected effect, or there was a total lack of effect, or they even increased ejection forces. The authors concluded that anyway, the tablets were superior in appearance.

Titanium carbide is by far the hardest material available for the treatment of surfaces.

Teflon coating has not proven to be wear-resistant enough to tolerate tableting.

Carbon in layer thickness of $0.1\text{ }\mu\text{m}$ – $10\text{ }\mu\text{m}$, doped with hydrogen in 5 at.%–30 at.% has proven to be extremely wear-resistant^[17] and to prevent sticking of tablets. The amorphous carbon layer is applied by CVP (chemical vapor deposition), which can also be used to apply coatings of metal, alloy, carbide, and nitride. It generally yields lower adhesion and superior wear resistance of the coatings, but the high temperatures necessary for the process (1000°C) would soften the steel and distort it. Ion plating is an alternative ensuring low adhesion and minimum distortion of the punches.

Alternative Materials

Inserted (lined) dies are fitted with an insert (liner) in the outer shell of the metal and consist of a much harder material such as tungsten carbide or a ceramic. Liners are used for compression of abrasive or corrosive materials.

The outer shell of steel protects the harder, more brittle liner from possible failure, e.g., by the die locking screw.

Maximum Pressure Tolerance

The pressure tolerance depends on the smallest diameter of the punch, e.g., the backing-off lathe at the punch tip and the cup depth. It is calculated from the load capacity of the tool steel. A guide for maximum pressure tolerance is given in Table 3.

Lifetime

Fatigue failure is cumulative because any over-stress inflicts microscopic damage. It correlates with the maximum stress in each loading cycle: a 25% reduction in stress may prolong the lifetime tenfold. It is advisable not to exceed the stress level over the maximum allowable limit for infinite lifetime; it is much better to change the design of the punch-tip cup in order to eliminate fatigue failure.

Average lifetime is most affected by granule composition and lubrication properties, lying between 200,000 and several millions of compression events.^[18]

Principal reasons for termination of punch life are damage to heads and tips, rolled-in or burred tip edges, pitted faces, distorted and/or flattened bisects or engravings, and undersized tip lands. For dies, it is the wear in the die bore that terminates lifetime, whereas for carbide lined dies it is often distortion leading to die screw groove. Increased clearances accelerate wear, e.g., by extrusion of

Table 3 Maximum pressure tolerated by round tools (kN); estimated values as a guideline

Diameter		Flat-faced	Flat with bevel	Concave (depending on cup depth)	Deep concave and modified ball

10 kN = 1 t.

(From Ref. [2].)

powder between punch and die. During lifetime the deflection of the upper punch in the turret can double, which leads to rolled-in punch tips. Cam design and cam track tolerances determine wear on punch heads with smaller tolerances used on modern machines prolonging punch life.

MAINTENANCE OF PUNCH SETS

Sets of toolings, i.e., upper punch, lower punch, and die, should not be interchanged. Therefore, they are usually marked by engraved numbers, punches at the neck, dies on the outer wall. Special care must be taken when toolings are fitted to the tablet press. Fitting instructions usually follow with the manual for the respective press. In general, careful aligning is crucial, for hands-on hints see Ref. 19 and ask the tooling manufacturer. Special maintenance kits useful for changing punches and containing a set of aids are available from press manufacturers and tooling manufacturers.

Immediately after the end of the production campaign, and in the case of long-lasting production cycles also during runs (e.g., daily), tooling should be carefully cleaned. Unless a special washing machine is used, warm soap water and a soft brush are suitable for thorough cleaning; if necessary, a few minutes in an ultra-sound bath can be helpful. Be careful not to scratch the surfaces! Upon rinsing with warm water, ethanol or isopropanol is used to remove any remaining oil. Removing punches and dies for washing takes a lot of time. Some tablet presses (e.g., from Fette, Korsch) are constructed in a way that enables interchangeability of the whole turret including tooling, and the cleaning of the turret takes place in a fully automatic washing machine at the same time as the rest of the tablet press is cleaned in place, which very much reduces turn-over-time, especially if two separate turrets are available.

Tooling should not be touched with bare fingers after washing, and usually all the tooling is thoroughly coated with an acid-free oil in order to prevent corrosion. Instead of expensive commercial products, paraffin and vaseline in pharmacopoeial quality are also suitable. Some users want to avoid all oiling as oil may contribute to sticking problems; in this case punches are washed with alcohol, possibly dusted with magnesium stearate, and stored in a humidity-controlled atmosphere.

Surface roughness and alteration in tooling dimensions are results of use and wear. Tooling surfaces should be frequently checked (magnifying glass). Timely polishing will prolong the lifetime of the tooling. Polishing can be done conventionally by hand on a lathe using ultra-fine polishing paste, polishing wool, and felt or a polishing brass brush. Alternatively, one can use cost-effective “drag

finishing” machines (e.g., from Otec, <http://www.otec.de>), which drag and rotate punches and dies through a granulate consisting of slightly abrasive particles coated with a special paraffin base. This process takes about 1 hr, depending on the abrasiveness of the granulate. The process does not round off the tooling but only decreases surface roughness and can be used whenever tooling appears dull or discolored. Furthermore, the punch barrels are polished too, which may help to prevent rough motion of the punches.

The wear pattern on punch heads, punch tips, and in die bores may indicate specific problems during tableting. Measuring dimensions of punches and dies is a task which has to be performed frequently and can be carried out computer-aided. Dimensions to be checked are overall length, cup depth, working length, diameters, tip diameter, and die bore dimensions. Use a micrometer.

For estimating the clearance of the upper punch in the turret and wear of the turret guide, it is easiest to measure the deflection of the upper punch tip, which should be approximately 100 μm . If it is more than 0.3 mm, the punches and/or guides are worn out.

Wear is unavoidable and it alters the dimensions of the tooling sets with time. It is, therefore, recommendable to use spare sets of tooling in regular turn-over in order to equalize wear of all tooling sets.

Storage cabinets for tooling should be clearly laid out for individual punch sets and protect them from clashing, dust, and humidity. Cabinets where punches lie or hang are available in many models made from different materials and with different degree of air-tightness.

A special tooling utility case system, consisting of individual punch and die trays enabling the combination of as many trays as needed, has an open design for easy inspection and cleaning (Ref. 20, available from Holland, <http://www.iholland.co.uk>).

Demands from GMP and the necessity of connecting tool sets to tablet products led to the introduction of “tooling management” with the help of special software (e.g., TM II from Natoli, <http://natoli.com/>, and Vali-Scan from Holland), where information on each individual encoded punch and die set is collected to provide a tooling life record. The software may be installed on a mobile trolley and the code on each individual tool will be checked while it is set onto the machine.

CONCLUSION

Many common tableting problems (e.g., sticking, capping, and corrosion) which cannot be overcome by optimizing the properties of the tableting material and/or the compression cycle, can possibly be solved by changing the tooling design. Options are the form,

the material and/or the finish of the respective toolings. Although there are software programs available for designing any possible punch tip shape and for theoretically calculating tablet volumes, surface areas, and other useful features (e.g., TabletCAD, from Natoli), this is no guarantee for being able to compress the respective tablets in practice. Moreover, it may be difficult to imagine on the basis of a punch design how the tablet itself would look like. For this purpose, simulated prototypes made quickly and inexpensively from a special plastic material can be bought under the trade name Elizatab (Elizabeth Carbide, <http://www.eliz.com>). As tooling manufacturers have been working with effective tablet designs for many years, it is generally recommendable to ask their advice whenever questions arise as to the design of tooling or tablets.

ACKNOWLEDGMENTS

The author wants to thank Mrs. S. Ritter, Ritter Pharma-Technik GmbH, Hamburg, Germany, for sharing her experience in tooling manufacture for production and research, Mr. Rod Wolstenholm, University of Tromsø, for doing the drawings, and Mrs. Gudrun Hansen, Tromsø, for help with the English.

TRANSDERMAL DRUG DELIVERY

Systemic as well as topical delivery of drugs via the transdermal route is limited by the low skin permeability which is attributed to the stratum corneum (SC), the outermost layer of the skin (1). The SC consists of disk-like dead cells (keratinocytes) containing keratin fibers and water, surrounded by densely-packed lipid bilayers. The highly-ordered structure of the lipid bilayers confers a highly impermeable character to the SC. A variety of approaches have been suggested to enhance transdermal drug transport. These include: 1) use of chemicals to either modify the skin structure or to increase the drug concentration in the transdermal patch (2,3); 2) applications of electric fields to create transient transport pathways [electroporation] (4,5) or to increase the mobility of charged drugs through the skin [iontophoresis] (6); and 3) application of ultrasound [sonophoresis] (7–56).

Sonophoresis was shown to enhance transdermal drug transport about half a century ago by Fellingner et al. (16) who showed that application of ultrasound increases transport of hydrocortisone across the skin. Following this study, attempts were made to enhance transdermal transport of more than 15 drugs including steroidal anti-inflammatory drugs such as hydrocortisone, dexamethasone; non-steroidal anti-inflammatory drugs such as salicylates and ibuprofen; anesthetic agents such as lidocaine; and proteins such as insulin. This chapter provides a review of these studies with emphasis on associated techniques, mechanistic studies, and safety.

GENERATION AND APPLICATION OF ULTRASOUND FOR SONOPHORESIS

Generation of Ultrasound

Ultrasound is a sound wave possessing frequencies above 20 kHz (57,58). These waves are characterized by two

main parameters: frequency and amplitude. Amplitude of ultrasound waves can be represented in terms of peak wave pressure (in Pascals) or in terms of intensity (in the units of W/cm^2). Ultrasound can be applied either continuously or in a pulsed manner. In the latter case, an additional parameter, duty cycle, is required to characterize ultrasound application. Duty cycle is the fraction of time for which ultrasound is ON.

Ultrasound is generated using a device referred to as a sonicator. It consists of an electrical signal generator which generates an electrical AC signal at the desired frequency and amplitude. This signal is applied across a piezo-electric crystal (transducer) to generate ultrasound. The thickness of the piezo-electric crystal is selected so that it resonates at the operating frequency. Sonicators operating at various frequencies in the range of 20 kHz to 3 MHz are available commercially and can be used for sonophoresis.

If a sonicator operating at the desired frequency is not available commercially, it is possible to assemble one using commercially available signal generators, amplifiers, and transducers. Such sonicators operating at frequencies of 10 MHz and 16 MHz have been assembled by Bommannan et al. (11). (For a discussion of the relevant methods for making a custom sonicator, see Ref. 11.)

For sonophoretic delivery, the desired drug is dissolved in a solvent and applied on the skin. Ultrasound is applied by contacting the transducer with the skin (see Fig. 1A–C) through a coupling medium to ensure a proper contact between the transducer and the skin. This medium can be the same as the solvent used to dissolve the drug or it can be a commercially available ultrasound coupling gel (for example, Aquasonic, Polar, NJ).

Transmission of Ultrasound from the Transducer to the Skin

Transmission through the medium

Ultrasound requires a coupling medium for transmission from the transducer to the desired tissue. The coupling

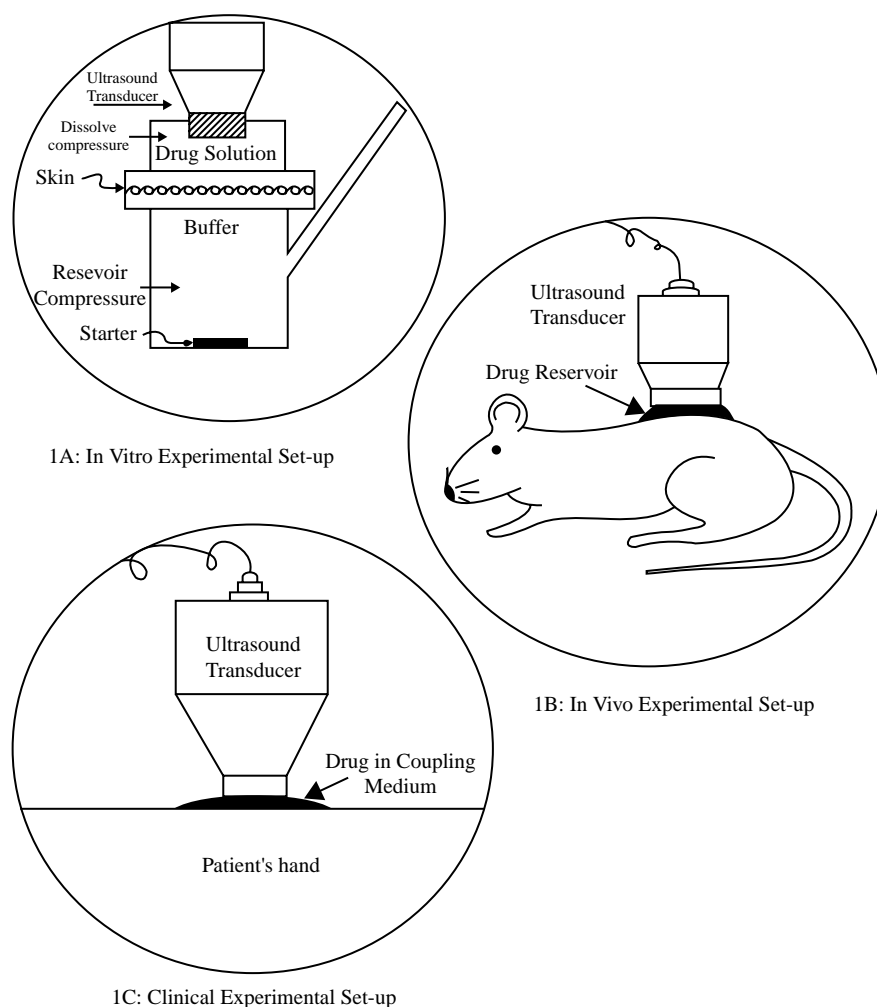

Fig. 1 Experimental set-up for sonophoresis delivery.

medium should result in proper transmission of ultrasound from the transducer to the skin. The transmissive properties of a medium are indicated by its acoustic impedance (Z). A coupling medium is appropriate for sonophoresis if its acoustic impedance (Z) is comparable to that of skin ($1.6 \times 10^6 \text{ kg/m}^2/\text{s}$). Z -values for various materials can be found in (57, 58). For example, water has a Z -value of $1 \times 10^6 \text{ kg/m}^2/\text{s}$ and is a reasonable coupling agent. Z -values for several media are listed in Table 1.

Absorption of ultrasound

Every medium absorbs ultrasound to a certain extent. The ability of a medium to absorb ultrasound is indicated by the absorption coefficient (α). The extent of absorption is given by the following equation.

$$f(\tau) = 1 - \exp(-\alpha\tau)$$

where $f(\tau)$ is the fraction of ultrasound intensity absorbed as the ultrasound beam propagates in a medium with absorption coefficient α and thickness τ . An estimation of α -values for various materials at various ultrasound frequencies may be found in Refs. (57, 58). In the case of water, the α -value is 0.0006 at an ultrasound frequency of 1 MHz, suggesting that a 1 cm thick column of water absorbs less than 0.1% of ultrasound (1 MHz) intensity, i.e., water is a reasonable coupling medium. Absorption coefficients for several media are listed in Table 1.

Ultrasound reflection

Ultrasound is reflected at the boundary of two media possessing different acoustic impedances. 99.99% of ultrasound is reflected at the air-water boundary when an ultrasound beam is incident upon it from either side. Hence occurrence of air bubbles should be minimized in

Table 1 Acoustic impedances and absorption coefficients of materials

Material	Acoustic impedance, Z ($\text{kg/m}^2/\text{s}$)	Absorption coefficient (α) at 1 MHz (cm^{-1})
Water	1.5×10^6	0.0006
Blood	1.6×10^6	0.028
Bone	6.3×10^6	3.22
Skin	1.6×10^6	0.62
Fatty tissue	1.54×10^6	0.14
Muscle	1.6×10^6	0.76
Air	0.0004×10^6	2.76

(From Hoogland, R., *Ultrasound Therapy*; Ernaf Nonius: Delft, Holland, 1986.)

the coupling medium in order to avoid ultrasound reflection. The reflection coefficient for various interfaces may be estimated from the acoustic impedances of two media forming the interface using equations described in (57, 58).

Selection of Ultrasound Parameters

Proper selection of ultrasound parameters is required to ensure safe and efficacious sonophoresis. Ultrasound parameters such as frequency, intensity, duty cycle, and distance of transducer from the skin influence the efficiency of sonophoresis. Below we present a general discussion of the role played by various ultrasound parameters in sonophoresis. Note that the objective of this discussion is not to point out the exact values of ultrasound parameters to be selected, but rather to present information regarding the dependence of sonophoretic enhancement on each parameter.

Ultrasound frequency

Ultrasound at various frequencies in the range of 20 kHz to 16 MHz has been used for sonophoresis. These studies of sonophoresis can be classified into three categories based on the ultrasound frequency used, i.e., therapeutic, high-frequency, and low-frequency ultrasound.

Therapeutic frequency ultrasound (1–3 MHz): This is the most commonly used ultrasound frequency range for sonophoresis. Specifically, over 90% of the previous studies of sonophoresis have been conducted using therapeutic ultrasound. A summary of these studies is provided in Table 2. Interestingly, in the therapeutic frequency range of 1–3 MHz, frequencies closer to 1 MHz

have been preferably used for sonophoresis. No reason has been given by investigators for the use of this particular frequency. Mitragotri et al. (36) reported that the sonophoretic enhancement in the therapeutic frequency range varies inversely with ultrasound frequency. They found that while 1 MHz ultrasound enhances transdermal transport of estradiol across human cadaver skin in vitro by 13-fold, 3 MHz ultrasound at the same intensity induces an enhancement of only 1.5-fold. They further hypothesized that the observed inverse dependence of sonophoretic enhancement on ultrasound frequency occurs since cavitation effects, which are primarily responsible for sonophoresis, vary inversely with ultrasound frequency (37, 59).

High-frequency ultrasound (above 3 MHz): Bommanan et al. (11, 12) performed sonophoresis of salicylic acid and lanthanum tracers across hairless rat skin in vivo using high-frequency ultrasound ($f = 2, 10$, and 16 MHz) (Table 3). They investigated the dependence of sonophoresis on ultrasound frequency in the high-frequency region and found that 10 MHz ultrasound is more effective in enhancing transdermal transport of salicylic acid than that at 16 MHz, which in turn, is more effective than that at 2 MHz. They proposed that the sonophoretic enhancement in the high-frequency region should vary directly with ultrasound frequency, though the anomalously high efficiency of sonophoresis at 10 MHz was due to higher efficiency of the transducer operating at that frequency.

Low-frequency ultrasound (below 1 MHz): Tachibana et al. (52, 53) have reported use of low-frequency ultrasound (48 kHz) to enhance transdermal transport of lidocaine and insulin across hairless mice skin. Very low-frequency ultrasound has also been used by Mitragotri et al. (37, 38) to enhance transport of various low-molecular weight drugs including salicylic acid, corticosterone as well as high-molecular weight proteins including insulin, γ -interferon, and erythropoietin across human cadaver skin in vitro. They investigated the dependence of sonophoretic enhancement in low-frequency region using two ultrasound frequencies, 20 and 40 kHz, and found that the sonophoretic enhancement of transdermal salicylic acid flux induced by 20 kHz ultrasound is up to 7-fold higher than that induced by 40 kHz ultrasound at the same intensity. The inverse dependence of sonophoretic enhancement on ultrasound frequency was hypothesized to occur due to inverse dependence of cavitation effects on ultrasound frequency (59).

Ultrasound intensity

Various ultrasound intensities in the range of 0.1–2 W/cm² have been used for sonophoresis. In most

Table 2 Literature reports of therapeutic sonophoresis

Drug	Molecular weight (Da)	Experimental system	Ultrasound conditions	Experimental conclusions ^a	Ref.
Caffeine	194	Human skin in vitro	1 MHz, 2 W/cm ²	0.2 ± 0.4	(37)

^a The experimental conclusions are reported either as statistically significant or insignificant enhancement or in terms of a quantitative ratio of sonophoretic and passive skin permeability.

^b Unpublished data by J. Kost and R. Langer.

cases, use of higher ultrasound intensities is limited by thermal effects. Several investigations have been performed to assess the dependence of sonophoretic enhancement on ultrasound intensity. Miyazaki et al. (41) found a relationship between the plasma concentrations of indomethacin transported across the hairless rat skin by sonophoresis (therapeutic conditions) and the ultrasound intensity used for this purpose. Specifically, the plasma indomethacin concentration at the end of three hours after sonophoresis (0.25 W/cm^2) was about 3-fold higher than controls at the same time. However, increasing intensity by 3-fold (to 0.75 W/cm^2) further increased sonophoretic enhancement only by 33%. Mortimer et al. (42) found that application of ultrasound at 1 W/cm^2 increased transdermal oxygen transport by 40% while that at 1.5 W/cm^2 and 2 W/cm^2 induced an enhancement by 50% and 55%, respectively.

In the very low-frequency ultrasound region (20 kHz), Mitragotri et al. (37) have reported that permeability of human skin in vitro to insulin increased by more than 100-fold as the ultrasound intensity increased from 12.5 to 125 mW/cm^2 . This variation of sonophoretic skin permeability with ultrasound intensity is quite different from that observed in therapeutic frequency region described above.

Pulse length

Ultrasound can be applied either in a continuous or a pulsed mode. A pulsed mode of ultrasound application is used many times because it reduces the severity of adverse side effects of ultrasound, such as thermal effects. However, pulsed application of ultrasound may have a significant effect on the efficacy of sonophoresis. As will be discussed later, cavitation effects, which play a crucial role in sonophoresis, vary significantly with the pulse length. For example, the cavitation threshold in an aqueous solution at 1 MHz changes from approximately 0.3 W/cm^2 (60) to 33 W/cm^2 (61) as the mode of ultrasound application changes from continuous to pulsed, with a pulse length of 1 ms applied every 10 ms. This is because under pulsed ultrasound, during the intervals between pulses, gas nuclei formed during the previous pulse have time to dissolve back into solution, and therefore, making it more difficult to cavitate the solution (62). Mitragotri et al. (36) reported that while a continuous application of therapeutic ultrasound (1 MHz, 2 W/cm^2) increased human skin permeability to estradiol by 13-fold, a pulsed application (2 ms pulses applied every 10 ms) did not significantly enhance transdermal estradiol flux. In very low-frequency ultrasound region, Kost et al. (28) reported that urea permeability of cuprophane membranes

increased from 6 to 56% as the ultrasound (20 kHz) pulse length increased from 100 to 400 ms (applied every second).

Distance of the transducer from the skin

The ultrasound pressure (or intensity) field around a transducer is quite complex. The intensity of the ultrasound passes through a series of maxima and minima in a region near the transducer and beyond a certain distance, decreases monotonically with distance. The region in which the ultrasound intensity passes through the series of minima and maxima is referred to as the near field, and the region beyond the near field is referred to as the far field. The length of the near field of a transducer having an area of 1 cm^2 operating at 1 MHz is 1.66 cm (57). In most of the experiments reported in the literature, for which ultrasound frequencies of 1 MHz or above have been used, the distance of the skin from the transducer was probably less than 1.66 cm. As a result, in most reported experiments, the skin was in the near-field region. In very low-frequency ultrasound region, Julian et al. (23) studied the effect of transducer distance on the sonophoretic permeability of benzoic acid through a polydimethylsiloxane membrane under low-frequency conditions. They observed that the effect of 20 kHz ultrasound on the permeability of the membrane is insensitive to the distance of the transducer from the membrane. This probably occurs because of the successive reflections of ultrasound waves in the diffusion cell which prevents any systematic pressure pattern from forming in the diffusion cell.

Ultrasound energy dose

In a recent systematic study of the dependence of 20 kHz sonophoresis on ultrasound parameters, Mitragotri et al. showed that the enhancement of skin permeability varies linearly with ultrasound intensity and ultrasound on-time (for pulsed ultrasound, ultrasound on-time equals the product of total ultrasound application time and duty cycle), while is independent of the ultrasound duty cycle. Based on those findings, the authors reported that there is a threshold energy dose for ultrasound induced transdermal drug transport. Once the threshold value is crossed, the enhancement of skin permeability varies linearly with the ultrasound energy dose (J/cm^2), which is calculated as the product of ultrasound intensity and ultrasound on-time. This result indicates that ultrasound energy dose can be used as a predictor of the effect of 20 kHz sonophoresis. The authors also indicated that it is important to determine the threshold energy dose for each individual sonophoresis system, for example, the

Table 3 Literature reports of high frequency sonophoresis

Drug	Molecular weight (Da)	Experimental system	Ultrasound conditions	Experimental conclusions ^a	Ref.
Salicylic acid	138	Hairless rat in vivo	2, 10, and 16 MHz 200 mW/cm ²	2–4 fold enhancement	(11)
Lanthanum tracers	—	Hairless rat in vivo	10 and 16 MHz 200 mW/cm ²	Significant enhancement	(12)

^aThe experimental conclusions are reported as statistically significant or insignificant enhancement.

real in vivo situation, because it may vary from system to system. Specifically, it may vary between different skin models, as well as with the ultrasound frequency and the distance of the transducer from the skin surface, etc.

PREVIOUS STUDIES OF SONOPHORESIS

Numerous attempts of sonophoresis have been performed over the last 40 years. As described earlier, these attempts can be classified into three categories: therapeutic frequency, high-frequency and low-frequency ultrasound.

Therapeutic Frequency Sonophoresis

The therapeutic ultrasound conditions correspond to a frequency in the range of 1–3 MHz and an intensity in the range of 0–2 W/cm². Therapeutic ultrasound has been attempted to enhance transdermal transport of more than 15 drugs (7–10, 14, 15, 18–22, 25, 22, 27, 28, 30–33, 36, 33, 42–45, 47–50, 55, 56, 63), a summary of which is provided in Table 2.

Historically, the transdermal route of drug administration has been considered for topical rather than systemic delivery of drugs. Accordingly, most of the sonophoresis experiments reported in Table 2 were intended for topical delivery of various drugs. Among all the drugs that have been used for sonophoresis, much attention has been focused on anti-inflammatory drugs. These include steroidal drugs such as hydrocortisone and dexamethasone and non-steroidal drugs such as indomethacin and salicylate. Sonophoresis of anti-inflammatory drugs offers an advantage over their passive topical delivery in that ultrasound may deliver drugs deeper into tissues. This is especially advantageous in the case of delivery of anti-inflammatory drugs to muscles which lie deeper into the body. Griffin et al. (18) reported that application of

ultrasound (1 MHz, 2 W/cm²) delivered hydrocortisone about 5 cm deep into pig tissues. This characteristic property of sonophoresis has been used effectively by these investigators to deliver hydrocortisone to joints for the treatment of rheumatoid arthritis.

The most commonly used technique of sonophoresis in these studies was to apply hydrocortisone in the form of an ointment on the skin and then apply ultrasound by keeping the transducer in contact with the ointment. In some cases, the transducer was moved in circular patterns to avoid a continuous exposure of a certain part of the skin to ultrasound. Although these studies were performed using different animal models, application techniques, hydrocortisone concentrations in the ointment, and exposure time, a measurable enhancement of hydrocortisone transport was reported in almost all cases. In contrast, most of the attempts to enhance transdermal transport of lidocaine and salicylates have been less successful. In the case of lidocaine, the sonophoretic enhancement was measured in terms of reduction of onset time for anesthesia or prolonging duration of anesthesia. In most cases, no significant effect of ultrasound application on either induction time or duration of anesthesia has been reported (55). Similarly sonophoresis of salicylates from ointments has not been found to induce any significant increase in plasma salicylate levels (14).

Literature data reported in Table 2 indicate that except in the case of steroids including hydrocortisone, dexamethasone, testosterone, estradiol, and corticosterone, application of therapeutic ultrasound results in either minor or no enhancement of transdermal drug transport. Mitragotri et al. (36) presented a hypothesis for this variation of sonophoretic enhancement from drug to drug based on their mechanistic conclusion that ultrasound induces disorganization of the SC lipid bilayers, thus increasing drug diffusivity and hence permeability of the SC. This mechanism suggests that drugs such as steroids which possess low passive diffusion coefficients through the SC bilayers (36) compared to those through the disordered SC bilayers should be significantly

enhanced by ultrasound application. On the other hand, drugs such as lidocaine and salicylic acid possessing a passive diffusion coefficient comparable to that through the disorganized bilayer phase (36) may not be significantly enhanced by ultrasound application. A mathematical equation was developed (39) to predict a priori whether application of therapeutic ultrasound under a typical condition, that is, 1 MHz, 2 W/cm² will enhance transdermal transport of a given drug:

$$E \approx \frac{K_{o/w}^{0.75}}{4 \times 10^4 P}$$

where E is sonophoretic enhancement of skin permeability (dimensionless), $K_{o/w}$ is the octanol–water partition coefficient, and P is the passive skin permeability (cm/h). A list of $K_{o/w}$ and P values for various drugs may be found in (64) and (65) respectively.

Over the last 20 years, transdermal route of delivery has been considered as a means for systemic drug administration. Over this period, sonophoresis has been attempted to enhance systemic transdermal delivery. Levy et al. (30) showed that 3–5 min. of ultrasound exposure (1 MHz, 1.5 W/cm²) increased transdermal permeation of mannitol and physostigmine across hairless rat skin in vivo by up to 15-fold. They also reported that the lag time typically associated with transdermal drug delivery was nearly-completely eliminated after exposure to ultrasound (30).

Although several attempts have been made to enhance transdermal drug transport using therapeutic ultrasound, a typical enhancement induced by therapeutic ultrasound is about 10-fold or smaller. This enhancement, may be sufficient for local delivery of certain drugs such as hydrocortisone, but is not sufficient for the systemic delivery of many drugs. Accordingly, despite of significant attention dedicated to sonophoresis, there is no commercially available sonophoresis system for the systemic drug delivery.

Low-Frequency Sonophoresis

Less attention has been given to sonophoresis in this ultrasound region (Table 4). Tachibana and Tachibana (51–53) reported that application of low-frequency ultrasound (48 kHz) enhances transdermal transport of lidocaine and insulin across hairless rat skin in vivo. They found that the blood glucose level of a hairless rat immersed in a beaker filled with insulin solution (20 U/ml) and placed in an ultrasound bath (48 kHz, 5000 Pa or 37 mm Hg) decreased by 50% in 240 min. (51). They also showed that application of ultrasound under similar conditions prolongs the anesthetic effect of transdermally administrated lidocaine in hairless rats (53) and enhances

transdermal transport of insulin in rabbits (52). Mitragotri et al. (37, 38) have shown that application of ultrasound at even lower frequencies (20 kHz) enhances transdermal transport of various low-molecular weight drugs including corticosterone, and salicylic acid as well as high-molecular weight proteins such as insulin, γ -interferon, and erythropoietin across the human skin in vitro (37) Table 4 provides a summary of the literature reports of low-frequency sonophoresis.

Transdermal transport enhancement induced by low-frequency ultrasound has been found to be much more significant than that induced by therapeutic ultrasound. For example, although application of therapeutic ultrasound has no effect on transdermal permeation of lidocaine, low-frequency ultrasound has been shown to significantly enhance lidocaine transport across hairless rat skin in vivo. Quantitatively, Mitragotri et al. (38) compared the enhancement ratios (ratio of the sonophoretic and passive permeabilities measured in vitro across human cadaver skin) induced by *therapeutic ultrasound* (1 MHz, 2 W/cm², continuous) (36) and *low-frequency ultrasound* (20 kHz, 125 mW/cm², 100 msec pulses applied every second) in the case of four permeants, butanol, corticosterone, salicylic acid, and sucrose. They found that the enhancement induced by low-frequency ultrasound is up to 1000-fold higher than that induced by therapeutic ultrasound (38).

Low-frequency ultrasound has been found to enhance transdermal transport of drugs which do not permeate skin passively, for example, large-molecular weight proteins. Application of low-frequency ultrasound (20 kHz, 125 mW/cm², 100 ms pulses applied every second) has been shown to enhance transdermal transport of proteins including insulin, γ -interferon, and erythropoietin across human cadaver skin in vitro (37). Figure 2 shows the variation of in vitro human skin permeability to insulin with ultrasound (20 kHz, 100 ms pulses applied every second) intensity. Skin insulin permeability increases by more than 100-fold as the ultrasound intensity increases from 12.5 mW/cm² to 125 mW/cm². It has also been shown that application of ultrasound under conditions the same as those mentioned above delivers therapeutic doses of insulin across hairless rat skin in vivo from a chamber glued on the rats back and filled with an insulin solution (100 U/ml) (37). Figure 3 shows blood glucose levels of diabetic rats during ultrasound-insulin treatment. Insulin-ultrasound treatment (20 kHz, 225 mW/cm², 100 ms pulses applied every second) reduces the blood glucose level of diabetic hairless rats from about 400–200 mg/dl (the blood glucose level of normal rats) in 30 min. A corresponding change in the plasma insulin levels was observed during sonophoresis. Normal hairless

^aThe experimental conclusions are reported either as statistically significant or insignificant enhancement or in terms of a quantitative ratio of sonophoretic and passive skin permeability.

rats possessed a plasma insulin level of 101 ± 31 picomolar while diabetic hairless rats possessed a value below our detection limit (34 picomolar). During sonophoresis, the levels of transdermally delivered human insulin in rat plasma reached a value of 77 (± 28) picomolar after 30 min. and a value of 178 (± 84) picomolar after 1 h (37). No significant change in the plasma concentration of indigenous rat insulin was observed during sonophoresis. These results indicate that sonophoresis at 20 kHz delivers therapeutic doses of insulin across hairless rat skin in vivo.

High-Frequency Sonophoresis

This region of ultrasound corresponds to a frequency higher than 3 MHz. Bommanan et al. (11) hypothesized that since the absorption coefficient of the skin varies directly with the ultrasound frequency, high frequency

ultrasound energy would concentrate more in the epidermis, thus leading to higher enhancements. In order to assess this hypothesis, they studied the effect of high-frequency ultrasound (2–15 MHz) on the permeability of salicylic acid (dissolved in a gel) through hairless guinea pig skin in vivo. They found that a 20 minute application of ultrasound (0.2 W/cm²) at a frequency of 2 MHz did not significantly enhance amount of salicylic acid penetrating the skin. However, 10 MHz ultrasound under otherwise same conditions resulted in about a 4-fold increase and 16 MHz ultrasound resulted in about a 2.5-fold increase in transdermal salicylic acid transport (11). They also investigated the effect of shorter (5 min.) ultrasound exposures under similar conditions on transdermal salicylic acid transport and found that while 10 MHz ultrasound enhances transdermal transport by 1.6-fold, that at 16 MHz enhances it by about 1.8-fold. Application of high-frequency ultrasound was also found to reduce the long lag time associated with transdermal

Fig. 2 Human skin permeability to insulin (37).

transport. Bommanan et al. (11) found that transdermally delivered salicylic acid appears much sooner in the urine if driven by sonophoresis than by passive permeation. These researchers also found that an electron dense tracer, such as lanthanum, was driven deep into the dermis by a 5 min. application of high-frequency ultrasound in hairless mouse *in vivo*.

MECHANISMS OF SONOPHORESIS

In order to understand the mechanisms of sonophoresis, it is important to identify various effects of ultrasound exposure on the human tissue since one or more of these effects may contribute to the mechanism of sonophoresis.

Fig. 3 Blood glucose levels of rats; ○ – diabetic hairless rats; △ – normal rats, ▲ – diabetic rats treated by sonophoresis and insulin for 30 min (37)

A brief description of the various biological effects of ultrasound is provided below.

Exposure Effects

Thermal effects

Absorption of ultrasound results in a temperature increase of the medium. Materials which possess higher ultrasound absorption coefficients, such as bones, experience severe thermal effects as compared to muscle tissues which have a lower absorption coefficient (α). α -values for several biological tissues can be found in (60,66) (Table 1). The absorption coefficient of a medium increases proportionally with the ultrasound frequency indicating that, the thermal effects of ultrasound are proportional to the ultrasound frequency. The increase in the temperature of a medium upon ultrasound exposure at a given frequency varies proportionally with the ultrasound intensity and exposure time. The thermal effects can be substantially decreased by pulsed application. For a detailed discussion of the thermal effects of ultrasound (60).

Acoustic streaming

Acoustic streaming, by definition, is the development of time independent large fluid velocities in a medium under the influence of an ultrasound wave. The primary causes of acoustic streaming are the reflections and other distortions of the wave propagation. Oscillations of cavitation bubbles may also contribute to acoustic streaming. The shear stresses developed by streaming velocities may affect the neighboring structures (67).

Cavitation effects

Cavitation is the formation of gaseous cavities in a medium upon ultrasound exposure. The primary cause of cavitation is the ultrasound-induced pressure variations in the medium. Cavitation involves either rapid growth and collapse of a bubble (transient cavitation) or slow oscillatory motion of a bubble in ultrasound field (stable cavitation). Cavitation affects tissues in several ways. Specifically, collapse of cavitation bubbles releases a shock wave which can cause structural alterations in its surroundings. Biological tissues contain numerous air pockets trapped in the fibrous structures which act as nuclei for cavitation upon ultrasound exposure. Accordingly, a significant cavitation activity is known to occur in biological tissues upon ultrasound exposure (60). The cavitation effects vary inversely with ultrasound frequency and directly with ultrasound intensity. Significant attention has been devoted to explore which of the

above mentioned phenomena plays an important role in sonophoresis.

Mechanisms of Therapeutic Sonophoresis

Mortimer et al. (42) performed sonophoresis of oxygen across frog skin *in vitro*. They found that the sonophoretic enhancement of transdermal oxygen transport depends on ultrasound intensity, rather than pressure amplitude. Based on this observation, they hypothesized that cavitation cannot be responsible for sonophoresis. They hypothesized that the observed enhancement occurs due to acoustic streaming in the solution around the skin (42). Levy et al. (30) performed an *in vitro* investigation of the roles played by thermal effects, cavitation, and mixing in sonophoretic enhancement of urea transport across polymer membranes. They found that the observed enhancement can not be explained by the thermal effects or mixing. In an attempt to elucidate the role played by cavitation, they performed sonophoresis experiments using degassed solutions. Since degassing a solution decreases the cavitation activity in the solution, they hypothesized that if a decrease in the sonophoretic enhancement is observed upon degassing, it would indicate the importance of cavitation. Indeed, they found that degassing procedure reduced the sonophoretic enhancement of urea permeation by 2-fold suggesting that cavitation may play a role in sonophoresis.

Cavitation occurs in a variety of mammalian tissues, including muscle, abdominal tissues, brain, cardiovascular tissues, and liver upon exposure to ultrasound at a variety of conditions (60). As explained earlier, the occurrence of cavitation in biological tissues is attributed to the existence of a large number of gas nuclei. These nuclei are gas pockets trapped in either intracellular or intercellular structures. Simonin et al. (68) hypothesized that cavitation occurs in the follicles of the skin upon ultrasound exposure and enhances transdermal permeation by convective velocities through follicles. However, no evidence was presented to support this hypothesis. Mitragotri et al. (36) presented results of the experiments indicating that cavitation inside the skin plays an important role in sonophoresis performed using therapeutic ultrasound.

In the first set of experiments, the known effect of static pressure on cavitation was utilized. It is known that cavitation in fluids and porous media (21) can be suppressed at high pressures. This effect is believed to occur due to the dissolution or collapse of the gaseous nuclei under the influence of pressure. Sonophoresis experiments were performed using skin compressed at

30 atm (between two smooth glass plates soaked in water placed in a compression press for two hours prior to sonophoresis experiments). They found that while application of ultrasound (1 MHz, 2 W/cm², continuous) enhances estradiol permeability of the normal human epidermis by 13-fold, the corresponding enhancement for compressed skin is only about 1.75-fold.

In the second set of experiments, the heat-stripped human cadaver skin was degassed (under a pressure of 0.05 mm Hg) prior to the permeability experiments. The authors hypothesized that when a skin piece soaked in buffer is subjected to high vacuum, the resulting low pressures should reduce the dissolved gas concentration in the buffer thereby forcing small gaseous nuclei in the skin to dissolve. When the degassed skin was exposed to ultrasound, once again, the effect of ultrasound on the estradiol permeability was minimal (1.5-fold), compared to 13-fold across the normal skin. Based on these two results, the authors concluded that cavitation inside the skin plays a major role in enhancing transdermal transport upon therapeutic ultrasound exposure. They provided the following hypothesis for the mechanism of sonophoresis performed using therapeutic ultrasound.

Ultrasound exposure in the therapeutic range causes cavitation in the keratinocytes of the stratum corneum. Oscillations of the ultrasound-induced cavitation bubbles near the keratinocyte-lipid bilayer interfaces may, in turn, cause oscillations in the lipid bilayers, thereby causing structural disorder of the SC lipids (Fig. 4). Shock waves generated by the collapse of cavitation bubbles at the interfaces may also contribute to the structure-disordering effect.

Since diffusion of permeants through a disordered bilayer phase can be significantly higher than that through a normal bilayer, transdermal transport in the presence of ultrasound is expected to be higher than passive transport.

Mechanisms of Low-Frequency Sonophoresis

Since cavitation effects in fluids vary inversely with ultrasound frequency (59), it is likely that cavitation effects should play an even more important role in low-frequency sonophoresis. Tachibana et al. (53) hypothesized that application of low-frequency ultrasound results into acoustic streaming in the hair follicles and sweat ducts of the skin, thus leading to enhanced transdermal transport. Mitragotri et al. (38) hypothesized that transdermal transport during low-frequency sonophoresis occurs across the keratinocytes rather than hair follicles. They provided

Fig. 4 Ultrasound-induced cavitation bubbles in stratum corneum.

the following hypothesis for the higher efficacy of low-frequency sonophoresis.

Cavitation induced by low-frequency ultrasound may cause disordering of the SC lipids. In addition, oscillations of cavitation bubbles may result in significant water penetration into the disordered lipid regions. This may cause the formation of aqueous channels through the intercellular lipids of the SC through which permeants may transport (Fig. 5). The occurrence of transdermal transport through aqueous channels across the disordered lipid regions may enhance transdermal transport as compared to passive transport because i) the diffusion coefficients of permeants through water, which is likely to primarily occupy the channels generated by ultrasound, are up to 1000-fold higher than those through the ordered lipid bilayers (38), and ii) the transport path length of these aqueous channels may be much shorter (by a factor up to 25 (69)) than that through the tortuous intercellular lipids in the case of passive transport.

This hypothesis also explains why low-frequency ultrasound can induce transdermal transport of drugs which exhibit very low passive transport. Drugs possessing low passive permeabilities are either i) hydrophilic, which makes their partitioning into the SC bilayers difficult, or ii) large in molecular size (for example, proteins), which reduces their diffusion coefficients in the SC. Low-frequency ultrasound may overcome both of these limitations by providing aqueous transport channels across the skin. Since these channels are filled with saline, hydrophilic drugs can easily partition into the SC. In addition, diffusion of drugs through water is much faster

than that through ordered lipid bilayer regions, thus allowing drugs to transport across the skin at a faster rate. Therefore, molecules such as hydrophilic drugs or proteins, may permeate skin with relative ease in the presence of low-frequency ultrasound.

Mechanisms of High-Frequency Sonophoresis

Bommanan et al. (12) performed sonophoresis of lanthanum tracers across hairless mice skin at an ultrasound frequency of 16 MHz in order to understand the transport pathways during high-frequency sonophoresis. They observed the skin under the electron microscope after sonophoresis and found that 5 min. of sonophoresis results in penetration of lanthanum tracers to dermal levels of the skin. They further reported that the tracer was patchily distributed within the intercellular lipid bilayers of the SC. They provided the following hypothesis for the mechanism of high-frequency sonophoresis. The micronuclei (air-pockets) present in the SC oscillate in response to oscillating pressure fields of ultrasound and eventually collapse. The oscillations of these bubbles result in enhanced skin permeation. They also hypothesized that the patchy distribution of the lanthanum tracer revealed in the micrographs corresponds to the location of oscillating air pockets in the SC. In a later report, Menon et al. (35) presented additional microscopic studies of the hairless mice skin after undergoing sonophoresis of lanthanum tracer. They reported the presence of long confluent channels in the intercellular lipids filled with lanthanum tracers in the hairless rat skin exposed to ultrasound. They

Fig. 5 Transdermal transport through the stratum corneum. (a) Passive and (b) during low-frequency sonophoresis.

presented the following hypothesis for the mechanism of sonophoresis: application of ultrasound opens and expands gas-filled cavities in the SC much like pumping air through a collapsed rubber tubing. Enhanced transport of drugs may then occur through these confluent channels across the SC.

SAFETY

The safety aspects of sonophoresis involve the reversibility of the skin barrier properties after turning ultrasound off, and the effect of ultrasound on the living parts of the skin and underlying tissues. Many reports exist in literature describing preliminary assessments of sonophoresis with respect to these two issues.

Recovery of the Skin Barrier Properties after Sonophoresis

Numerous reports exist to suggest that application of therapeutic ultrasound (1–3 MHz, 0–2 W/cm²) does not induce any irreversible change in the skin permeability to drugs *in vivo*. Quantitative measurements of estradiol transport across human skin (*in vitro*) have also shown that application of therapeutic ultrasound (1 MHz, 2 W/cm²) does not induce any statistically significant irreversible change in skin barrier properties (36). Similar studies have also been performed using very low-frequency ultrasound (20 kHz, 125 mW/cm², 100 ms pulses applied every second) to assess whether application of low-frequency ultrasound results in any permanent loss of the barrier properties of skin measured in terms of water permeability (38). It has been found that in the case of a 1 h long

ultrasound exposure, the skin permeability to water measured within 2 h post-exposure was comparable to the passive skin permeability to water. In the case of a 5-h long ultrasound exposure, the skin permeability 2 h post-exposure was about 6 times higher than the passive permeability to water. However, this value continued to decrease, and was within a factor of 2 of the passive skin water permeability 12 h post-exposure. Studies have also been performed (35) to assess whether application of high-frequency ultrasound induces any irreversible damage to the barrier properties of the skin measured in terms of trans-epidermal water loss (TEWL) across hairless mice skin exposed to high-frequency ultrasound (16 MHz). No significant difference in TEWL values of the skin exposed to ultrasound and that not exposed to ultrasound was found (35).

Biological Effects of Low-Frequency Ultrasound

Ultrasound over a wide frequency range has been used in medicine over last century. For example, therapeutic ultrasound (1–3 MHz) has been used for massage, low-frequency ultrasound has been used in dentistry (23–40 kHz) (70, 71), and high-frequency ultrasound (3–10 MHz) has been used for diagnostic purposes (66). In view of this, significant attention has been dedicated to investigate the effects of ultrasound on biological tissues. However, no conclusions have been reached regarding the limiting ultrasound conditions required to ensure safe exposure.

As described earlier, ultrasound affects biological tissues via three main effects, thermal effects, cavitation effects, and acoustic streaming. Conditions under which these effects become critical are given below (60).

Thermal effects may be important when

1. The tissue has a high protein content.
2. A high intensity continuous wave ultrasound is used.
3. Bone is included in the heated volume.
4. Vascularization is poor.

Cavitation may be important when

1. Low-frequency ultrasound is used.
2. Gassy fluids are exposed.
3. Small gas-filled spaces are exposed.
4. The tissue temperature is higher than normal.

Streaming may be important when

1. The medium has an acoustic impedance different from its surroundings.
2. The fluid in the biological medium is free to move.
3. Continuous wave application is used.

Numerous investigators have performed histological studies of animal and human skin exposed to ultrasound under various conditions in order to assess the effect of ultrasound on living skin cells. Levy et al. (30) exposed in vivo hairless rat skin to therapeutic ultrasound (1 MHz, 1.5 W/cm² continuous wave or 3 W/cm² pulsed wave, 3–5 min) and reported no damage to the skin. Nevertheless, Machet et al. (72) reported both epidermal and dermal alteration of human and hairless mouse skin when exposed to therapeutic ultrasound in vitro (3.3 MHz, 3 W/cm², 10 min). The authors proposed that a combined cavitation and thermal effect could explain these cellular lesions. Due to the higher likelihood of occurrence of cavitation under low-frequency ultrasound, the effect of low-frequency ultrasound on skin histology has drawn the most attention in the recent years. Tachibana et al. (52) exposed rabbit skin to 105 kHz ultrasound (5000 Pa, 5-s pulses applied at 5-s intervals, for 90 min) and reported no inflammation or destruction of skin. Mitragotri et al. (37) performed histological studies of hairless rat skin exposed to 20 kHz ultrasound (125 mW/cm², 100-ms pulses applied every second, for 1 h) and found no damage to the epidermis and underlying living tissues. In a more recent studies on skin microscopy, Yamashita et al. (54) exposed both human skin in vitro and hairless mouse skin in vivo to 48 kHz ultrasound at 0.5 W/cm² for 5 min, and reported that there was slight and complete removal of keratinocytes from human skin and hairless mouse skin, respectively. From the above reports, we can deduce that the effect of ultrasound, especially in the low-frequency range, on living skin cells strongly depends on the ultrasound parameters, i.e., frequency, intensity, exposure time and duty cycle. Further research focusing on safety

issues is required to evaluate limiting ultrasound parameters for safe exposure.

CONCLUSIONS

Application of ultrasound enhances transdermal drug transport, a phenomenon referred to as sonophoresis. Proper choice of ultrasound parameters including ultrasound energy dose, frequency, intensity, pulse length, and distance of transducer from the skin is critical for efficient sonophoresis. The numerous attempts made over the last 50 years can be classified into three categories: therapeutic frequency, high-frequency and low-frequency ultrasound; the first represents the most commonly used ultrasound condition for sonophoresis, although recently, attention has been more focused on low- and high-frequency conditions. Mechanistic experiments performed by several investigators suggest that cavitation plays a major role. It has been suggested that cavitation disorganizes the lipid bilayers of the skin through which enhanced transport of drugs may occur. Various studies have indicated that application of ultrasound under conditions used for sonophoresis does not cause any permanent damage to the skin or underlying tissues, although more work is required before arriving at definite conclusions regarding the safety of ultrasound exposure.

INTRODUCTION

Ultrasonic nebulizers use ultrasonic energy to convert liquid, usually an aqueous solution, into an aerosol for inhalation. They are used to deliver β_2 -agonists, corticosteroids, antiallergics, anticholinergics, and antiviral and mucolytic agents to the respiratory tract (1). Recent innovations have increased the popularity of nebulizers, both ultrasonic and air-jet, and new devices with improved portability, compared with traditional models, are capable of generating aerosols with high respirable fractions (deep lung delivery) with a high drug output. Nebulized drugs may be inhaled during normal tidal breathing through a mouthpiece or face mask, permitting their use for patients, such as the hospitalized, the elderly, children, and patients with arthritis, who experience difficulties with other devices. Nebulizers represent ideal delivery systems for drugs that cannot be conveniently formulated into pressurized metered-dose inhalers (pMDIs) or dry powder inhalers (DPIs) or when the therapeutic dose is too large for delivery with these systems.

Ultrasonic nebulizers were first developed in the 1960s and were initially used for air humidification in respiratory care units (2). Generally, ultrasonic nebulizers have higher mass outputs than do air-jet nebulizers, in which compressed gas is used as a means of generating the aerosol. However, this is achieved at the expense of a large aerosol droplet size (3–7). Consequently, the majority of ultrasonically generated aerosols have a mean droplet size considered unsuitable for efficient targeting of a drug to the alveolar region of the lung. However, the size distribution of droplets within aerosols produced by ultrasonic nebulization is generally less than that from air-jet nebulizers. Nevertheless, the generated aerosols are polydisperse in nature, and as with air-jet nebulizers, they require baffles to remove the larger droplets from the emitted aerosol. Because ultrasonic nebulizers have a high mass output, with increased droplet concentration, which is independent of the airflow, the duration of nebulization

is shorter than with air-jet nebulizers. This, together with their quieter mode of operation, may make them particularly attractive to patients. Ultrasonic nebulizers are reported to produce bronchodilator responses comparable with those of air-jet nebulizers and pMDIs (8).

MECHANISM OF AEROSOL GENERATION

The energy required to atomize a liquid is produced by a piezoelectric crystal transducer, usually a synthetic ceramic material, vibrating at a high frequency (1–3 MHz). When an alternating electric current is applied, the crystal shrinks and expands and the resultant vibrations are transmitted to the nebulized fluid, either directly or via a coupling liquid, usually water. A fountain of liquid is produced at the liquid surface, with large droplets being emitted from its apex and a “fog” of small droplets being produced from the lower part.

Fig. 1 illustrates the two mechanisms proposed for the processes of liquid disintegration and aerosol generation within ultrasonic nebulizers (9). The capillary-wave theory relates to the production of capillary waves in the bulk liquid. These waves constructively interfere to form peaks and a central geyser. When the amplitude of the applied energy is sufficiently high, the crests of the capillary waves break off, and droplets are formed. The rate of generation of capillary waves is dependent on both the physicochemical properties of the nebulized fluid and the intensity of the ultrasonic vibration. Mercer (3) used Eq. 1 to calculate the threshold amplitude for the generation of capillary waves:

$$A = 4 \frac{\nu}{f\lambda} \quad (1)$$

where A is the threshold amplitude, ν is the kinematic viscosity of the liquid, f is the acoustic frequency, and λ the capillary wavelength. When the amplitude exceeds the threshold value by a factor of approximately four, droplets are formed. Lang (10) noted that the mean droplet size generated from thin liquid layers was proportional to

the capillary wavelength on the liquid surface. Using an experimentally determined factor of 0.34, the droplet diameter D is given by Eq. 2;

$$D = 0.34\lambda \quad (2)$$

where D is the number median diameter and λ is the capillary wavelength. Lobdell (11) concurred with these findings and calculated a theoretical value of 0.36 for the proportionality constant. The capillary wavelength can be calculated from Kelvin's equation, as in Eq. 3:

$$\lambda = (8\pi\gamma/\rho f^2)^{1/3} \quad (3)$$

where γ is the surface tension, ρ is the density, and f the acoustic frequency. When γ is in mN/m (dyne/cm), ρ is in g/cm³, and f is in megacycles/s, then D is given in micrometers. Good correlation exists between calculated and experimentally derived values (12).

The second mechanism proposed for aerosol generation is based on the piezoelectric crystal operating at low frequency and imparting vibrations to the bulk liquid. This results in the formation of cavitation bubbles, which move to the air-liquid interface (13). The internal pressure within the bubbles equilibrates with that of the atmosphere, causing their implosion. When this occurs at the liquid surface, portions of the liquid break free from the turbulent bulk liquid, resulting in droplet formation. The dependence of atomization on cavitation phenomena has been demonstrated for frequencies between 0.5 and 2.0 MHz (14, 15). Boguslavskii and Eknadiosyants (16) combined these theories with their proposal that droplet formation resulted from capillary waves initiated and driven by cavitation bubbles.

NEBULIZER DESIGN

Ultrasonic nebulizers exist in a number of basic designs that differ in the configuration of the piezoelectric crystal transducer, nebulizer chamber, baffles, and auxiliary airflow systems (Fig. 2) (9). Once the aerosol cloud is generated from the nebulizer fluid, it is transferred from the chamber and made available to the patient. Ultrasonic nebulizers produce a large number of droplets per unit volume, which tend to aggregate and settle in the absence of air circulating through the device. Larger droplets impact on the baffles or internal surfaces to return to the reservoir surface for recirculation under the influence of gravity. Smaller droplets leave the device aided by an internal fan (e.g., Medix Electronic[®], Easimist[®]) or by entrainment into the inspiratory flow of the patient (e.g., DeVilbiss Pulmosonic[®]). Air velocity over the reservoir surface may be modified by fan speed (and flow constrictors), thereby influencing both droplet size and aerosol output rate. For instance, changing the fan speed

setting of the Sonix 2000[®] (Medix) ultrasonic nebulizer can vary flow output between 1 ml per min and 1 ml per 6 min. The important design features influencing mass output and the particle size of the generated aerosols are summarized in Table 1.

Whereas air-jet nebulizers are usually disposable or sterilizable, ultrasonic nebulizers are too expensive to be produced as disposable units and are thus used repeatedly (17), running the risk of bacterial contamination (18). Cleaning nebulizers and connecting tubing is difficult, and the transfer of Gram-negative bacteria between nebulization equipment and patients has been reported (19).

Although most ultrasonic devices share a basic design, some novel devices have been developed. The Respimat[®] (Boehringer Ingelheim) offered direct delivery of a metered dose from a valve similar to that used in pMDIs to the surface of a vibrating crystal (2.5 MHz). Although the mass median aerodynamic diameter (MMAD) of the aerosol generated was closed to 10 μm , generally considered too large for effective inhalation therapy, equivalence to an equivalent pMDI formulation was claimed (20).

The Bepak Piezo Electric Actuator[®] is a novel aerosol delivery system based on a piezoelectric crystal combined with an electroformed mesh (Fig. 3). It produces droplets of “adjustable” size from a single metered drop or fluid reservoir (21). The mesh hole dimension (as small as 3 μm) determines the size of the droplets produced, whereas the size and density of the holes control the rate of fluid delivery. These can be varied according to the formulation. Although solutions are more readily nebulized, suspensions can be aerosolized if the particle size of the

Fig. 3 Schematic diagram of the sprayhead of the Bepak Piezo Electric Actuator. (Reproduced courtesy of Bepak plc, UK.)

suspended particles is two to three times smaller than the mesh size.

More recently, The Technology Partnership has created several new forms of a perforated mesh atomizer known as TouchSpray[®] (22). TouchSpray devices deliver suspensions without requiring these to be formulated with small suspended particles. Furthermore, they can produce small droplets from large mesh holes. For example, TouchSpray devices can deliver 5 μm droplets of suspensions containing normally micronized drug suspensions, which typically include particles of 3 μm or larger. These droplets can be produced by devices having mesh hole sizes of 15 μm . TouchSpray allows small droplets to be produced from solutions. A review of the development of perforated mesh devices is given in Humberstone et al. (23). An inhalation droplet spray plume produced by the TouchSpray is shown in Fig. 4.

Future devices are likely to be hybrids of ultrasonic nebulizer technology and pMDI or DPI technology. Vibrating transducer or grids, incorporated into pMDIs, could break down large propellant droplets that would otherwise be wasted into a more respirable size range. Alternatively, the dependence of DPIs on patient-generated turbulent airstreams could be minimized by deaggregating powder by vibrational elements within the inhalation device or by generating aerosols electrostatically (Spiros[®], Dura).

AEROSOL DROPLET SIZE

The efficacy of a therapeutic inhalation aerosol depends on its ability to penetrate the respiratory tract. This is

Fig. 4 Inhalation droplet spray plume produced by TouchSpray device. (Reproduced courtesy of The Technology Partnership plc, UK.)

primarily dependent on the particle size of the particles or droplets. To penetrate to the peripheral (respiratory) airways, aerosols generally require a size less than approximately $5\text{--}6\text{ }\mu\text{m}$, with a size less than $2\text{ }\mu\text{m}$ being optimal for alveolar deposition (24, 25).

Clinical performance is often predicted from in vitro measurements of the droplet size of an aerosol. Nebulized aerosols are usually assessed by a multistage liquid impinger (MSLI), cascade impactor, or laser diffraction methods. The MSLI and cascade impactors comprise a series of progressively finer jets and collection plates, permitting fractionation of aerosols according to their MMADs (26). Problems associated with the cascade impactors for the assessment of nebulized aerosols are that the high flow rates involved (typically $28\text{--}90\text{ L/min}$) give rise to rapid solvent evaporation and droplet entrainment. Additionally, these inertial impaction techniques are invasive, laborious, and time-consuming. Alternatively, nebulized aerosols may be sized by passing the spray through a beam of a laser diffraction analyzer. The volume or mass median diameter is then calculated from

the generated diffraction pattern. Provided the liquid density is known, the MMAD can be calculated.

Numerous investigators have compared the aerosol droplet size of nebulized aerosols from ultrasonic and air-jet devices (3, 4, 6, 27–31). Because droplet size is inversely proportional to the acoustic frequency, smaller droplets are generated from ultrasonic devices with higher frequencies. Ultrasonic nebulizers with high operating frequencies ($2\text{--}3\text{ MHz}$) are capable of generating droplets of sizes comparable to air-jet devices. However, devices with low frequencies ($<0.5\text{ MHz}$) tend to generate droplets outside the respirable range (4, 32). Most commercially available ultrasonic nebulizers have an operating frequency between 1 and 2 MHz. Although these produce aerosol droplets, which are significantly larger than those produced by air-jet nebulizers (3, 4), the size distributions are generally less polydisperse (3, 33).

NEBULIZATION TIME, DRUG OUTPUT, AND RESIDUAL VOLUME

Patient compliance with prescribed nebulization regimes is primarily determined by the duration of the therapy. Nebulizer fluids may be atomized for a set period, or more usually, a measured volume of therapeutic liquid is nebulized to “dryness.” The time taken to achieve this is directly related to the volume to be delivered. However, not all the fluid in the nebulizer can be atomized, and some fluid remains associated with the baffles, internal structures, and walls of the nebulizer as the “dead” or “residual” volume (34). The proportion of fluid remaining as the residual volume and thus unavailable to patients is higher for smaller fill volumes.

Ultrasonic devices typically produce a much larger fluid output per unit of time than do jet nebulizers. Although Sterk et al. (4) suggested that high airflow through these devices resulted in lower droplet concentrations per unit volume than for air-jet nebulizers, more recent findings indicate that the reduced volume of dilution air in modern ultrasonic devices gives a more concentrated aerosol cloud. Ultrasonic nebulizers may retain a higher residual volume than do comparable air-jet nebulizers (35), but they show less tendency to increase the solute concentration within the nebulizer chamber during operation (27, 29).

In comparing DeVilbiss ultrasonic and jet devices, Newman et al. (29) reported shorter nebulization times for the ultrasonic devices with higher fluid outputs. Furthermore, the air-jet devices tended to increase the concentration of drug in the nebulizer chamber more

than did the ultrasonic counterparts. The output from nebulizers comprises droplets of drug solutions and suspensions and solvent vapor, which saturates the outgoing air, causing solute concentration to increase during nebulization. Because ultrasonic nebulizers generally have higher fluid outputs and larger droplet sizes than do air-jet nebulizers, there is more solvent available within the dense aerosol cloud to saturate the outgoing air. Thus, the changes in solute concentration within the dead volume are much smaller than for air-jet devices.

THERMAL EFFECTS

Excess energy within the nebulizer is converted to heat, causing the temperature of the liquid in the reservoir to increase until the input energy balances the energy removed by evaporation and by conduction to the surroundings and circulating air (12). The temperature of a liquid in an ultrasonic nebulizer may thus increase by as much as 20°C above ambient temperature during use (6, 36). This results in changes in the properties of the fluid, including surface tension and viscosity. Although such changes may affect the aerosol particle size characteristics and overall drug output, little variation was seen during prolonged operation of Medix Electronic or Easimist nebulizers (37) or when the temperature in a DeVilbiss Aerosonic nebulizer was increased using a heating coil (38).

Warming may have a beneficial effect. For instance, the temperature of fluids atomized in air-jet nebulizers decreases by approximately 10–15°C during use (34, 39), resulting in bronchoconstriction in some asthma sufferers (40). Bronchoconstriction, which is most marked at 5°C, disappears at 37°C and thus may be minimized by using an ultrasonic device. Furthermore, when solutions of drugs with low solubility are to be nebulized, ultrasonic nebulizers, which warm the solutions, may be preferable (36) to air-jet devices, which cool them and may cause precipitation (39). However, the heat generated may harm heat-labile materials such as diethylenetriaminepentaacetic acid (^{99}mTc -DTPA) (41), proteins (31), and some antibiotic solutions (42). Thus, ultrasonic nebulizers are specifically prohibited for aerosolization of recombinant human deoxyribonuclease (rhDNase) (1).

FORMULATION OF NEBULIZER FLUIDS

Respiratory solutions are the mainstay of nebulized inhalation therapy. These typically contain drug dissolved

in aqueous, isotonic solvent systems, with the inclusion of cosolvents (e.g., ethanol) if necessary. Suspensions are less common for nebulization, although corticosteroid preparations such as budesonide are available. Antioxidant and antimicrobial preservatives may be included in the formulations; however, some (e.g., sodium metabisulfate, benzalkonium chloride, EDTA) may have paradoxical effects and cause coughing and bronchoconstriction (43). To prevent this, "preservative-free" unit dose products are marketed. Isotonicity is generally achieved using sodium chloride. Although iso-osmotic solutions of pH 3–8.5 are usually employed, the osmolality and pH may change during use, resulting in bronchospasm (44).
